EXITING FROM QE

by

February 2016

Abstract

We develop a regime-switching SVAR (structural vector autoregression) in which the monetary policy regime, chosen by the central bank responding to economic conditions, is endogenous and observable. QE (quantitative easing) is one such regime. The model incorporates the exit condition for terminating QE. We apply it to Japan, a country that has experienced three QE spells. Our impulse response analysis shows that an increase in reserves raises output and inflation and that exiting from QE can be expansionary.

Keywords: quantitative easing, structural VAR, observable regimes, Taylor rule, impulse responses, Bank of Japan.

This is a substantially revised version of Hayashi and Koeda (2014). We are grateful to Toni Braun for continued encouragement and consultation. We also thank James Hamilton, Yuzo Honda, Tatsuyoshi Okimoto, Etsuro Shioji, George Tauchen, and participants at a San Francisco Fed conference for useful comments and suggestions. The research reported here was supported by grants-in-aid from the Ministry of Education, Culture, Sports, Science, and Technology of the Japanese government (grant number 25285097 and 26870124).
1 Introduction and Summary

Quantitative easing, or QE, is an unconventional monetary policy that combines zero policy rates and positive excess reserves held by depository institutions at the central bank. This paper uses an SVAR (structural vector autoregression) to study the macroeconomic effects of QE. Reliably estimating such a time-series model is difficult because only several years have passed since the adoption of QE by central banks around the world. We are thus led to examine Japan, a country that accumulated, by our count, 130 months of QE as of December 2012. Those 130 QE months come in three installments, which allows us to evaluate the effect of exiting from QE. We end the sample period in 2012 because the Bank of Japan, under the new governor since 2013, appears to have embarked on a regime that is very different from those observed in our sample period.

We will start out by documenting for Japan that reserves are greater than required reserves (and often several times greater) when the policy rate is below 0.05% (5 basis points) per year. We say that the zero-rate regime is in place if and only if the policy rate is below this critical rate. Therefore, the regime is observable and, since reserves are substantially higher than the required level, the zero-rate regime and QE are synonymous. There are three spells of the zero-rate/QE regime: March 1999 - July 2000 (call it QE1), March 2001 - June 2006 (QE2), and December 2008 to date (QE3). They account for the 130 months. For most of those months the BOJ (Bank of Japan) made a stated commitment of not exiting from the zero-rate regime as long as inflation is below a certain threshold.

Our SVAR, in its simplest form, has two monetary policy regimes: the zero-rate regime in which the policy rate is very close to zero, and the normal regime of positive policy rates. It is a natural extension of the standard recursive SVAR\(^1\) to accommodate both the zero lower bound on the policy rate and the exit condition. There are four variables: inflation, output (measured by the output gap), the policy rate, and excess reserves, in that order. The first two equations of the

\(^1\) See Christiano, Eichenbaum, and Evans (1999) for the recursive SVAR. Their SVAR orders variables by placing non-financial variables (such as inflation and output) first, followed by monetary policy instruments (such as the policy rate and measures of money), and financial variables (such as stock prices and long-term interest rates).
system are reduced-form equations describing inflation and output dynamics. The reduced-form coefficients are allowed to depend on the regime. The third is the Taylor rule providing a shadow policy rate. Due to the zero lower bound, the actual policy rate cannot be set equal to the shadow rate if the latter is negative. The fourth equation specifies the central bank’s supply of excess reserves under QE. The exit condition requires that the central bank ends the zero-rate regime only if the shadow rate is positive and the inflation rate is greater than or equal to a certain threshold. The regime is endogenous because its occurrence depends on inflation and output through the zero lower bound and the exit condition.

We describe the effects of various monetary policy changes by a counter-factual analysis in a style similar to the standard IR (impulse response) analysis. To evaluate the effect of a change in the policy rate, the reserve supply, the regime that occurs in the base period \( t \), or a combination thereof, we compare the projected path of inflation and output conditional on the baseline history up to \( t \) with the path conditional on the alternative history that differs from the baseline history with respect to the policy variable(s) in question in \( t \). The response profile, namely the difference between the two projected paths at various horizons, reduces to the standard IR function (adapted to nonlinear models) if the two histories differ in only one respect. We find:

- QE is expansionary. When the current regime is the zero-rate/QE regime, the response of output and inflation to an increase in excess reserves is positive. This is consistent with the finding in the literature on the macro effects of QE to be reviewed in the next section. The significance of our finding is that we allow the regime to vary endogenously in periods after the base period.

- Surprisingly, exiting from QE can be expansionary. We set \( t = July \) 2006, the month the zero-rate/QE regime was terminated, and consider an alternative and counter-factual history of not exiting from QE in \( t \). The two histories differ in \( t \) not just in the regime but also in the policy rate and excess reserves. We find that output and inflation are lower under the counter-factual alternative of extending QE to July 2006.

After a literature review in Section 2 and making a case for the monetary policy regime observability in Section 3, we devote four sections on the baseline model. Section 4 describes our
four-variable SVAR. Section 5 reports our parameter estimates. Section 6 conducts the
counter-factual analysis which produces the two main findings reported above. Since these
findings can be controversial, we devote Section 7 for a discussion of possible reasons why these
conclusions might obtain.

The findings delivered by the simple baseline SVAR model hold up when we extend it to
encompass two features about excess reserves found specifically in Japanese data. First, not all
QEs are alike. In the “weak” QE, as observed in QE1 (March 1999 - July 2000), excess reserves
behave differently than in the “strong” QE, as in QE2 and QE3, when they are large and
responsive to inflation and output. Second, there are a few incidents of positive excess reserves
under positive interest rates. The response profiles in our counter-factual analysis are similar when
these two features are incorporated.

These two extensions are presented in Section 8. It also examines robustness to several
variations of the baseline model. Section 9 is a brief conclusion.

2 Relation to the Literature

The literature on the macroeconomic effects of QE is growing rapidly. Here in this section, we
restrict our attention to those studies that use time-series data to evaluate the macroeconomic
effect of QE; studies utilizing DSGE (dynamic stochastic general equilibrium) models and those
whose main concern is the yield curve implications of the zero-rate policy will be mentioned in
Section 7. Remarkably, all the time-series studies we came across with report that QE raises
inflation and output. In one strand of the literature, the measure of QE is price-based. Kapetanios
et. al. (2012) and Baumeister and Benati (2013) include the yield spread in their VARs (vector
autoregressions). The QE measure in Wu and Xia (2014) is the shadow policy rate properly
defined.

More relevant to our paper are those studies that use quantities as the QE measure. The
earliest and also the cleanest is Honda et. al. (2007) for Japan. Their QE measure is reserves,
which was the target used by the BOJ (Bank of Japan) during the zero-rate period of 2001
through 2006. Their recursive VAR of prices, output, and reserves, estimated on monthly data for
the zero-rate period, shows that the IR of prices and output to an increase in reserves is positive. A more elaborate SVAR with the same QE measure, estimated by Schenkelberg and Watzka (2013) on Japanese monthly data for the period of 1995-2010 (when the policy rate was below 1%), yields the same conclusion. The QE measure in Gambacorta et. al. (2014) is the level of central bank assets. Their VAR is recursive except that they allow the central bank assets and the financial variable (VIX in their case) to interact contemporaneously in the same month. The sample period is January 2008-June 2011. They overcome the shortness of the sample by utilizing data from eight advanced economies including Japan.

Another way to deal with the small sample problem is to include the normal period of positive policy rates but allow the model parameters to vary over time in some specific ways. Kimura and Nakajima (2013) use quarterly Japanese data from 1981 and assume two QE spells (2001:Q1 - 2006:Q1 and 2010:Q1 on). Their TVAR (time-varying parameter VAR) takes the zero lower bound into account by forcing the variance of the coefficient in the policy rate equation to shrink during QEs. Fujiwara (2006) and Inoue and Okimoto (2008) apply the hidden-state Markov-switching SVAR to Japanese monthly data. They find that the probability of the second state was very high in most of the months since the late 1990s. For those months, the IR of output to an increase in the base money is positive and persistent.

Because the regime is chosen by the central bank to honor the zero lower bound, or more generally, to respond to inflation and output, it seems clear that the regime must be treated as endogenous. And, as will be argued in the next section, a strong case can be made for the observability of the monetary policy regime. None of the papers with quantitative QE measures cited so far treat the regime as observable and endogenous. Furthermore, their IR analysis does not allow the regime to change in the future.

The regime in Iwata and Wu (2006) and Iwata (2010), in contrast, is observable and endogenous. It is necessarily endogenous because the policy rate in their VAR, being subject to the zero lower bound, is a censored variable. Our paper differs from theirs in several important respects. First, our SVAR incorporates the exit condition as well as the zero lower bound. Second and crucially, we consider IRs to regime changes. This allows us to examine the macroeconomic effect of exiting from QE. As already mentioned in the introduction, our paper has a surprising
result on this issue. Third, their IR exhibits the price puzzle (see Figure 3 of Iwata (2010)). We show in our paper that, at least for the output gap measure we consider, the price puzzle is to a large extent resolved if we allow the equilibrium real interest rate to vary over time.2

3 Identifying the Zero-Rate Regime

Identification by the “L”

We identify the monetary policy regime on the basis of the relation between the policy rate and excess reserves. Figure 1a plots the policy rate against $m$, the excess reserve rate defined as the log of the ratio of the actual to required levels of reserves.3 Because the BOJ (Bank of Japan) recently started paying interest on reserves, the vertical axis in the figure is not the policy rate $r$ itself but the net policy rate $r - \tilde{r}$ where $\tilde{r}$ is the rate paid on reserves (0.1% since November 2008). It is the cost of holding reserves for commercial banks.

The figure shows a distinct L shape. Excess reserves are positive for all months for which the net policy rate $r - \tilde{r}$ is below some very low critical rate, and zero for most, but not all, months for which the net rate is above the critical rate.4 Those months with $m > 0$ and with very low net policy rates will form the zero-rate period. To examine those months with $m > 0$ but with positive net policy rates, we magnify the plot near the origin in Figure 1b. The dotted horizontal red line is the critical rate of $r - \tilde{r} = 0.05\%$ (5 basis points). The dots off the vertical axis (for

2 Braun and Shioji (2006) show that the price puzzle is pervasive for both the U.S. and Japan in the recursive SVAR model. For Japan, they use monthly data from 1981 to 1996 and find that a large and persistent price puzzle arises for a variety of choices for the financial variables including commodity prices, the Yen-Dollar exchange rate, oil prices, the wholesale price index, and the 10-year yield on government bonds. They also find that the puzzle arises when each of those financial variables are placed third after inflation and output.

3 The policy rate in Japan is the overnight uncollateralized interbank rate called the “Call rate”. The level of reserves and the policy rate are the averages of daily values over the reserve maintenance period to be consistent with the required reserve system in place. See the data appendix for more details.

4 The two months of significantly positive excess reserves when the policy rate is about 8% are February and March of 1991, when the Gulf war was about to end.
which \( m > 0 \) and over the red dotted line can be divided into two groups. The first is composed of the filled squares above the dotted red line. They come from the period July 2006 - November 2008, between spells of very low net policy rates. The observation in this group with the largest value of \( m \) is \((m_t, r_t - \bar{r}_t) = (0.21, 0.49\%)\) for \( t = \) September 2008, the time of the Lehman crisis. The second group above the red dotted line is indicated by filled circles. Their value of \( m \) is much lower than for the first group. They come from the late 1990s and the early 2000s when the Japanese financial system was under stress. The largest \( m \) is \((m_t, r_t - \bar{r}_t) = (0.089, 0.22\%)\) for \( t = \) October 1998 when the Long-Term Credit Bank went bankrupt.

Because the supply curve of reserves should be horizontal when the policy rate is positive, the second group represents the demand for excess reserves when the shock to reserve demand is large for precautionary reasons. Regarding the first group (the filled squares), it appears that, until the Lehman crisis, precautionary demand was not the reason for commercial banks to hold excess reserves. Industry sources indicate that, after several years of near-zero interbank rate with large excess reserves, the response by smaller-scale banks when the policy rate turned positive from essentially zero was to delay re-entry to the interbank market.\(^5\) As more banks returned to the interbank market, however, aggregate excess reserves steadily declined. This declining trend continued until Lehman, when smaller banks as well as large ones sharply increased reserves. In the empirical analysis below, we set \( m \) to zero for those months leading up to Lehman (or, equivalently, we constrain the lagged \( m \) coefficient in the reduced form to zero). On the other hand, we view the positive excess reserves from September 2008 until the arrival of the next zero-rate period as representing demand and leave the excess reserve value as is.

We say that the zero-rate regime is in place if and only if the net policy rate \( r - \bar{r} \) is below

---

\(^5\) A breakdown of excess reserves by type of financial institutions since 2005, available from the BOJ’s homepage, shows that large banks quickly reduced their excess reserves after the termination in July 2006 of the zero-rate policy while other banks (regional banks, foreign banks, and trust banks) were slow to adjust. The average of excess reserves for July 2006 - August 2008 is only 0.1\% of the average for January 2005 - June 2006 for large banks and 5.4\% for other banks. In order to exploit the arbitrage opportunity presented by the positive interbank rates, banks need to train their employees afresh. The reason commonly cited for the slow adjustment (see, e.g., Kato (2010)) is that medium- to small-scale banks, after several years of near-zero overnight rates, didn’t find it profitable to immediately return to the interbank market by incurring this re-entry cost.
the critical rate of 0.05% (5 annual basis points). Since there are no incidents of near-zero excess reserves when the net rate is below the critical rate (the minimum is 0.041, see Table 3 below), the zero-rate regime is synonymous with QE (quantitative easing). For this reason we will use the term “the zero-rate regime” and “QE” interchangeably. Under our definition, there are three periods of the zero-rate/QE regime in Japan:

**QE1:** March 1999 - July 2000,

**QE2:** March 2001 - June 2006,

**QE3:** December 2008 to date.

Figure 2a has the time-series bar chart of the excess reserve rate \( m \). The three QE spells are indicated by the shades. As just explained, the thin bars between QE2 and the Lehman crisis of September 2008 will be removed in the empirical analysis below.\(^6\) QE1 looks different from QE2 and QE3. The value of \( m \) during QE2, much higher than during QE1, was supply-determined because the level of reserves (i.e., the current account balance) during the spell was the BOJ’s target. It seems clear that the same was true for QE3 because, although no longer an explicit target, the current account balance was the frequent subject during the BOJ’s policy board meetings. QE2 and QE3 will be referred to as the period of “strong” QE. QE1 is the period of “weak” QE because the value of \( m \), although positive, is much lower than under “strong” QE. For the most part, we will treat QE1 as a historical aberration. That is, the SVAR of the next section and the counter-factual analysis of Section 6 will assume that the only type of QE under the zero-rate regime is the “strong” type. A full analysis of both types of QE is postponed until Section 8.\(^7\)

---

\(^6\) The value of \( m \) for December 1999 was very high, about 0.9, due to the Y2K problem. This Y2K spike has been replaced by the sample mean of \( m \) over QE1 in the bar chart.

\(^7\) We do this for four reasons. First, the exposition of the SVAR and the counter-factual analysis are much more transparent if there are only two regimes, one of which is the normal regime. Second, the model with just one QE type may be adequate for economies other than Japan, notably the U.S. Third, the market’s expectations embedded in the reduced form may well be that the “weak” QE would never be repeated. Fourth, as will be shown in Section 8, the results will not change greatly if the model is extended to two QE types.
Consistency with BOJ Announcements

Our dating of the zero-rate regime, which is based solely on the net policy rate, agrees with announced monetary policy changes. To substantiate this claim, we collected relevant announcements of the decisions made by the BOJ’s Monetary Policy Meetings (Japanese equivalent of the U.S. FOMC, held every month and sometimes more often) in Table 1. For example, the end of our QE1 is followed by the 11 August 2000 BOJ announcement declaring the end of a zero-rate policy, and the 14 July 2006 BOJ announcement follows our QE2’s end. The 19 March 2001 announcement marks the start of our QE2. The only discrepancy between our QE darting and the BOJ announcements is the start of QE1. The 12 February 1999 BOJ announcement, which is to guide the policy rate as low as possible, is more than one month before the start of our QE1 (whose first month is the March 1999 reserve maintenance period). It took a while for the BOJ to lower the policy rate averaged over a reserve maintenance period below 0.05%.

The Exit Condition

Several authors have noted that the BOJ’s zero-interest rate policy is a combination of a zero policy rate and a stated commitment to a condition about inflation for exiting from the zero-rate regime. Indeed, the BOJ statements collected in Table 1 indicate that during our three zero-rate/QE spells, the BOJ repeatedly expressed its commitment to an exit condition stated in terms of the year-on-year (i.e., 12-month) CPI (Consumer Price Index) inflation rate. For example, during QE1’s very first reserve maintenance period (March 16, 1999 - April 15, 1999), the BOJ governor pledged to continue the zero rate “until the deflationary concern is dispelled” (see the 13 April 1999 announcement in the table). To be sure, the BOJ during the first twelve months of QE3 did not publicly mention the exit condition, until December 18, 2009. However, as Ueda (2012), a former BOJ board member, writes about this period: “At that time some observers thought that the BOJ was trying to target the lower end of the understanding of price stability, which was 0-2%.” (Ueda (2012, p. 6)) We will assume that the exit condition was in place during this episode as well.

---

The last several months of QE2 (ending in June 2006) require some discussion. Table 2 has data for those and surrounding months. The 9 March 2006 announcement declared that the exit condition was now satisfied. However, the actual exit from the zero-rate regime did not take place until July 2006. To interpret this episode, we note that the year-on-year CPI inflation rate (excluding fresh food) for March 2006 was significantly above 0%, about 0.5%, if the CPI base year is 2000, but merely 0.1% (as shown in the table) if the base year is 2005. The 2005 CPI series was made public in August 2006. We assume that the BOJ postponed the exit until July because it became aware that inflation with the 2005 CPI series would be substantially below inflation with the 2000 CPI series.

4 The Regime-Switching SVAR

This section presents our four-variable SVAR (structural vector autoregression). Strictly for expositional clarity, the model here makes two simplifying assumptions about the excess reserve rate $m$ (the log of the actual-to-required reserve ratio). First, it is zero under the normal regime of positive policy rates. Second, the zero-rate regime is equated with “strong” QE. That is, there is only one type of QE and $m$ under QE is supply-determined by the central bank. Those assumptions will be lifted in Section 8.

The Standard Three-Variable SVAR

As a point of departure, consider the standard three-variable SVAR in the review paper by Stock and Watson (2001). The three variables are the monthly inflation rate from month $t-1$ to $t$ ($p_t$), the output gap ($x_t$), and the policy rate ($r_t$). The inflation and output gap equations are reduced-form equations where the regressors are (the constant and) lagged values of all three variables. The third equation is the Taylor rule that relates the policy rate to the contemporaneous values of the year-on-year inflation rate and the output gap. The error term in this policy rate

---

9 In Stock and Watson (2001), the three variables are inflation, the unemployment rate, and the policy rate. We have replaced the unemployment rate by the output gap, because Okun’s law does not seem to apply to Japan. The sampling frequency in Stock and Watson (2001) is a quarter.
equation is assumed to be uncorrelated with the errors in the reduced-form equations. This error covariance structure, standard in the structural VAR literature (see Christiano, Eichenbaum, and Evans (1999)), is a plausible restriction to make, given that our measure of the policy rate for the month is the average over the reserve maintenance period from the 16th of the month to the 15th of the next month.

As is standard in the literature (see, e.g., Clarida et al. (1998)), we consider the Taylor rule with interest rate smoothing. That is,

\[
(Taylor \ rule) \quad r_t = \rho_r r_t^* + (1 - \rho_r) r_{t-1} + \nu_{rt}, \quad r_t^* \equiv \alpha_r + \beta_r^* \begin{bmatrix} \pi_t \\ x_t \end{bmatrix}, \quad \nu_{rt} \sim N(0, \sigma_r^2). \tag{4.1}
\]

Here, \( \pi_t \), defined as \( \pi_t \equiv \frac{1}{12} (p_t + \cdots + p_{t-11}) \), is the year-on-year inflation rate over the past 12 months. If the adjustment speed parameter \( \rho_r \) equals unity, this equation reduces to \( r_t = r_t^* + \nu_{rt} \).

We will call \( r_t^* \) the desired Taylor rate.

**Introducing Regimes**

The three-variable SVAR just described does not take into account the zero lower bound on the policy rate. Given the interest rate \( \tilde{r}_t (\geq 0) \) paid on reserves, the lower bound is not zero but \( \tilde{r}_t \).

The Taylor rule with the lower bound, which we call the censored Taylor rule, is

\[
(\text{censored Taylor rule}) \quad r_t = \max \left[ \rho_r r_t^* + (1 - \rho_r) r_{t-1} + \nu_{rt}, \tilde{r}_t \right], \quad \nu_{rt} \sim N(0, \sigma_r^2). \tag{4.2}
\]

Now \( \rho_r r_t^* + (1 - \rho_r) r_{t-1} + \nu_{rt} \) is a shadow rate, not necessarily equal to the actual policy rate.

It will turn out useful to rewrite this in the following equivalent way. Define the monetary policy regime indicator \( s_t \) by

\[
s_t = \begin{cases} 
P & \text{if } \rho_r r_t^* + (1 - \rho_r) r_{t-1} + \nu_{rt} > \tilde{r}_t, \\
Z & \text{otherwise.}
\end{cases} \tag{4.3}
\]
Then the censored Taylor rule can be written equivalently as

\[
\begin{cases}
\rho_r r^*_t + (1 - \rho_r) r_{t-1} + v_{rt}, \quad v_{rt} \sim N(0, \sigma^2_r) & \text{if } s_t = P, \\
\tilde{r}_t & \text{if } s_t = Z.
\end{cases}
\]  

(4.4)

Note that \( r_t - \tilde{r}_t = 0 \) if and only if \( s_t = Z \). Thus, consistent with how we identified the regime in the previous section, we have \( s_t = P \) (call it the normal regime) if the net policy rate \( r_t - \tilde{r}_t \) is positive and \( s_t = Z \) (the zero-rate regime) if the rate is zero. An outside observer can tell, without observing the shadow Taylor rate, whether the regime is P or Z.

The Exit Condition

We have thus obtained a simple regime-switching three-variable SVAR by replacing the Taylor rule by its censored version. We expand this model to capture the two aspects of the zero-rate regime discussed in the previous section. One is the exit condition, the additional condition needed to end the zero-rate regime when the shadow rate \( \rho_r r^*_t + (1 - \rho_r) r_{t-1} + v_{rt} \) has turned positive. As was documented in the previous section, the condition set by the BOJ is that the year-on-year inflation rate be greater than or equal to some threshold. We allow the threshold to be time-varying. More formally, we retain the censored Taylor rule (4.4) but modify (4.3) as follows.

\[
\begin{cases}
\text{If } s_{t-1} = P, \quad \tilde{s}_t = \begin{cases}
P & \text{if } \rho_r r^*_t + (1 - \rho_r) r_{t-1} + v_{rt} > \tilde{r}_t, \\
Z & \text{otherwise.}
\end{cases} \\
\text{If } s_{t-1} = Z, \quad \tilde{s}_t = \begin{cases}
P & \text{if } \rho_r r^*_t + (1 - \rho_r) r_{t-1} + v_{rt} > \tilde{r}_t \text{ and } \pi_t \geq \pi_t + v_{\pi t}, \quad v_{\pi t} \sim N(0, \sigma^2_{\pi}), \\
Z & \text{otherwise.}
\end{cases}
\end{cases}
\]  

(4.5)
We assume that the stochastic component of the threshold (\(v_{\pi t}\)) is i.i.d. over time.\(^{10}\) It is still the case that \(r_t - \bar{r}_t = 0\) if and only if \(s_t = Z\), regardless of whether \(s_{t-1} = P\) or \(Z\). As before, an outside observer can tell the current monetary policy regime just by looking at the net policy rate: \(s_t = P\) if \(r_t - \bar{r}_t > 0\) and \(s_t = Z\) if \(r_t - \bar{r}_t = 0\).

**Adding \(m\) to the System**

The second extension of the model is to add the excess reserve rate \(m_t\) (defined, recall, as the log of actual-to-required reserve ratio) to the system. This variable, while constrained to be zero in the normal regime \(P\), becomes a monetary policy instrument in the zero-rate regime \(Z\). It is a censored variable because excess reserves cannot be negative. If \(m_{st}\) is the (underlying) supply of excess reserves, actual \(m_t\) is determined as

\[
m_t = \begin{cases} 
0 & \text{if } s_t = P, \\
\max \left[ m_{st}, 0 \right] & \text{if } s_t = Z.
\end{cases}
\]

(4.6)

Our specification of \(m_{st}\) is as in Eggertson and Woodford (2003); it depends on the current value of inflation and output with partial adjustment:

\[
(m_{st} \text{ supply}) \quad m_{st} \equiv \alpha_s + \beta_s \begin{bmatrix} \pi_t \\ x_t \end{bmatrix} + \gamma_s m_{t-1} + v_{st}, \; v_{st} \sim N\left(0, \sigma_s^2\right).
\]

(4.7)

The speed of adjustment is \(1 - \gamma_s\). We expect the inflation (\(\pi_t\)) and output (\(x_t\)) coefficients to be negative, i.e., \(\beta_s < 0\), since the central bank would increase excess reserves when deflation worsens or output declines.

**Allowing the Reduced Form Coefficients to Depend on the Regime**

The central bank sets the policy rate under the normal regime and the excess reserve level under the zero-rate regime. Since the policy rule is different — very different — between the two regimes, the reduced-form equations describing inflation and output dynamics could shift with the regime. If the private sector in period \(t\) sets \((p_t, x_t)\) in full anticipation of the period’s regime

---

\(^{10}\) If we introduced serial correlation by allowing \(v_{\pi_t}\) to follow the AR(1) (the first-order autoregressive process) for example, we would have to deal with an unobservable state variable (which is \(v_{\pi t-1}\) for the AR(1) case) appearing only in an inequality. The usual filtering technique would not be applicable.
to be chosen by the central bank, the period \( t \) reduced form should depend on the date \( t \) regime. Since we view this to be a very remote possibility, we assume that the reduced-form coefficients and error variance and covariances in period \( t \) depend, if at all, on the lagged regime \( s_{t-1} \).

**To Recapitulate**

This completes our exposition of the regime-switching SVAR on four variables, \( p_t \) (monthly inflation), \( x_t \) (the output gap), \( r_t \) (policy rate), and \( m_t \) (the excess reserve rate). The underlying sequence of events leading up to the determination of the two policy instruments \((r_t, m_t)\) can be described as follows. At the beginning of period \( t \) and given the previous period’s regime \( s_{t-1} \), nature draws two reduced-form shocks, one for inflation and the other for output, from a bivariate distribution. The reduced-form coefficients and the error variance-covariance matrix may depend on \( s_{t-1} \). This determines \((p_t, x_t)\) and hence the 12-month inflation rate \( \pi_t \equiv \frac{1}{12}(p_t + \cdots + p_{t-11}) \).

The central bank then draws three policy shocks \((v_{rt}, v_{\pi t}, v_{st})\) from \( \mathcal{N}(\mathbf{0}, \text{diag}(\sigma_r^2, \sigma_{\pi}^2, \sigma_s^2)) \). It can now calculate: \( \rho_r r_t^* + (1 - \rho_r) r_{t-1} + v_{rt} \) (the shadow Taylor rate given in (4.1)), \( \pi_t + v_{\pi t} \) (the inflation threshold shown in (4.5)), and \( m_{st} \) (excess reserve supply, given in (4.7)). Suppose the previous regime was the normal regime (so \( s_{t-1} = P \)). Then the bank picks \( s_t = P \) if \( \rho_r r_t^* + (1 - \rho_r) r_{t-1} + v_{rt} > r_t \) and \( s_t = Z \) otherwise. Suppose, on the other hand, that \( s_{t-1} = Z \). Then the bank terminates the zero-rate/QE regime and picks \( s_t = P \) only if \( \rho_r r_t^* + (1 - \rho_r) r_{t-1} + v_{rt} > \tilde{r}_t \) and \( \pi_t \geq \bar{\pi} + v_{\pi t} \). If \( s_t = P \), the bank sets \( r_t \) to the shadow rate and the market sets \( m_t \) to 0; if \( s_t = Z \), the bank sets \( r_t \) at \( \tilde{r}_t \) and \( m_t \) at \( \max[m_{st}, 0] \).

The model’s variables are \((s_t, y_t)\) with \( y_t \equiv (p_t, x_t, r_t, m_t) \). Assume, as we do in the empirical analysis, that the reduced-form equations involve only one lag. To be clear about the nature of the stochastic process the model generates, assume, only here and temporarily, that the monthly inflation rate \( p_t \) rather than the 12-month inflation rate \( \pi_t \) enters the Taylor rule and the excess reserve supply equation and that \( \tilde{r}_t \) (the rate paid on reserves) is constant (at zero). Then the model with the exit condition is a time-invariant mapping from \((s_{t-1}, y_{t-1})\) and the i.i.d. date \( t \) shocks (consisting of the reduced-form shocks and the policy shocks \((v_{rt}, v_{\pi t}, v_{st})\)) to \((s_t, y_t)\). Therefore, the stochastic process generated by the model, \( \{s_t, y_t\}_{t=0}^\infty \), is a first-order Markov process. Now, with the 12-month inflation \( \pi \) rather than the 1-month inflation \( p \) in the Taylor rule
and in the excess reserve supply equation, the number of lags for $y$ is not 1 but 11 and the mapping is from $(s_{t-1}, y_{t-1}, y_{t-2}, ..., y_{t-11})$ and the date $t$ shocks. With the time-varying exogenous variable $\tilde{r}_t$, the mapping is not time-invariant.

For later reference, we write the mapping as

$$(s_t, y_t) = f(s_{t-1}, y_{t-1}, y_{t-2}, ..., y_{t-11}, (\varepsilon_t, v_{rt}, v_{\pi t}, v_{sl}); \theta_A, \theta_B, \theta_C).$$

(4.8)

Here, $\varepsilon_t$ is the bivariate reduced-form shock in date $t$ and $v$’s are the monetary policy shocks. $(\theta_A, \theta_B, \theta_C)$ form the model’s parameter vector. The first subset of parameters, $\theta_A$, is the reduced-form parameters describing inflation and output dynamics. Because we allow the reduced form to depend on the (lagged) regime, the parameter vector $\theta_A$ consists of two sets of parameters, one for $P$ and the other for $Z$. The second subset, $\theta_B$, is the parameters of the Taylor rule (4.5), while the third subset, $\theta_C$, describe the excess reserve supply functions (4.7). More precisely,

$$\theta_B = \left(\alpha_r, \beta_r, \rho_r, \sigma_r, \pi, \sigma_\pi \right)_{(2\times1)}, \quad \theta_C = \left(\alpha_s, \beta_s, \gamma_s, \sigma_s \right)_{(2\times1)}.$$

The mapping is not time-invariant only because of the presence of the exogenous variable.

5 Estimating the Model

This section has three parts: a summary of Appendix 4 about the derivation of the model’s likelihood function, a summary of the data description of Appendix 1, and a presentation of the estimation results.

The Likelihood Function (Summary of Appendix 4)

Were it not for regime switching, it would be quite straightforward to estimate the model because of its block-recursive structure. As is well known, the regressors in each equation are predetermined, so the ML (maximum likelihood) estimator is OLS (ordinary least squares). With regime switching, the regressors are still predetermined, but regime endogeneity needs to be taken into account as described below.
Thanks to the block-recursive structure, the model’s likelihood function has the convenient property of additive separability in a partition of the parameter vector, so the ML estimator of each subset of parameters can be obtained by maximizing the corresponding part of the log likelihood function. More specifically, the log likelihood is

\[
\log \text{likelihood} = L_A(\theta_A) + L_B(\theta_B) + L_C(\theta_C).
\]

The parameter vectors \( \theta_A, \theta_B, \) and \( \theta_C \) have been defined at the end of the previous section.

The first term, \( L_A(\theta_A)\), being the log likelihood for the reduced-form for inflation and output, is entirely standard, with the ML estimator of \( \theta_A \) given by OLS. That is, the reduced-form parameters for regime P can be obtained by OLS on the subsample for which the lagged regime \( s_{t-1} \) is P, and the same for \( Z \). There is no need to correct for regime endogeneity because the reduced form errors for period \( t \) is independent of the lagged regime. Regarding the reserve supply parameters \( \theta_C \), which are estimated on subsample with \( s_t = Z \), the censoring implicit in the “max” operator in (4.6) calls for Tobit with \( m_t \) as the limited dependent variable. However, since there are no observations for which \( m_t \) is zero on subsample \( Z \) (which makes the zero-rate regime synonymous with QE as noted in Section 3), Tobit reduces to OLS. There is no need to correct for regime endogeneity because the current regime \( s_t \) is independent of the error term of the excess reserve supply equation.

Regime endogeneity is an issue for the second part \( L_B(\theta_B)\), because the shocks in the Taylor rule and the exit condition, \( (\psi_{rt}, \psi_{rt}) \), affect regime evolution. If the exit condition were absent so that the censored Taylor rule (4.2) were applicable, then the ML estimator of \( \theta_B \) that controls for regime endogeneity would be Tobit on the whole sample composed of P and \( Z \); subsample P, on which \( r_t > \overline{r}_t \), provides “non-limit observations” while subsample \( Z \), on which \( r_t = \overline{r}_t \), is “limit observations”. With the exit condition, the ML estimation is only slightly more complicated because whether a given observation \( t \) is a limit observation or not is affected by the exit condition as well as the lower bound.

**The Data (Summary of Appendix 1)**

The model’s variables are \( p \) (monthly inflation), \( x \) (output gap), \( r \) (the policy rate), and \( m \) (the excess reserve rate).
The excess reserve rate $m$ is the log of actual to required reserves. We have already mentioned that actual reserves and the policy rate $r$ for the month are the averages over the reserve maintenance period. The graph of $m$ has been shown in Figure 2a. Recall that we defined the zero-rate/QE regime $Z$ as months for which the net policy rate $r_t - \tilde{r}_t$ is less than 5 basis points. We ignore the variations of $r$ during the regime by setting $r_t - \tilde{r}_t$ to zero for all observations in subsample $Z$.

The output measure underlying the output gap $x$ is a monthly GDP series obtained by combining quarterly GDP and a monthly comprehensive index of industry activities available only since January 1988. This determined the first month of the sample period. For potential GDP, we use the official estimate by the Cabinet Office of the Japanese government (the Japanese equivalent of the U.S. Bureau of Economic Analysis). It is based on the Cobb-Douglas production function with the HP (Hodrick-Prescott) filtered Solow residual. The output gap is then defined as 100 times the log difference between actual and potential GDP. Monthly GDP and potential GDP are in Figure 2b. It shows the well-known decline in the trend growth rate that occurred in the early 1990s, often described as the (ongoing) “lost decade(s)”. It also shows that the output gap has rarely been above zero during the lost decades. The fluctuations in potential output toward the end of the sample period reflect the earthquake and tsunami of March 2011.

The inflation rate $p$ is constructed from the CPI (consumer price index). The relevant CPI component is the so-called “core” CPI (the CPI excluding fresh food), which, as documented in Table 1, is the price index most often mentioned in BOJ announcements. (Confusingly, the core CPI in the U.S. sense, which excludes food and energy, is called the “core-core” CPI.) We made adjustments to remove the effect of the increase in the consumption tax rate in 1989 and 1997 before performing a seasonal adjustment. We also adjusted for large movements in the energy component of the CPI between November 2007 and May 2009.\footnote{It appears that those large movements were discounted by the BOJ. The monetary policy announcement of August 19, 2008 (http://www.boj.or.jp/en/announcements/release_2008/k080819.pdf), which stated that the policy rate would remain at around 50 basis points, has the following passage: “The CPI inflation rate (excluding fresh food) is currently around 2 percent, highest since the first half of 1990s, due to increased prices of petroleum products and food.”} The year-on-year (i.e.,...
12-month) inflation rate $\pi_t$ equals $\pi_t = \frac{1}{12}(p_t + \cdots + p_{t-11})$. Figure 2c has $\pi_t$ since 1988 along with the policy rate $r_t$ and the trend growth rate, defined as the 12-month growth rate of the potential output series shown in Figure 2b.

Simple statistics of the relevant variables are in Table 3. Since we set the net policy rate $r_t - \bar{r}_t$ to zero under Z and since $\bar{r}_t = 0$ during QE1 and QE2 and $\bar{r}_t = 0.1\%$ during QE3, the policy rate $r_t$ itself is 0% during QE1 and QE2 and 0.1% during QE3.

**Parameter Estimates**

Having described the estimation method and the data, we are ready to report parameter estimates. We start with $\theta_B$.

**Taylor rule with exit condition ($\theta_B$).**

Most existing estimates of the Taylor rule for Japan end the sample at 1995 because the policy rate shows very little movements near the lower bound since then. In our ML estimation, which can incorporate the lower bound on the policy rate, the sample period can include all the many recent months of very low policy rates. On the other hand, the starting month is January 1988 at the earliest because that is when our monthly output series starts.

Before commenting on the ML estimate shown in Table 4 below, we state two considerations underpinning our specification of the Taylor rule.

- (variable real interest rates) We have been treating the intercept in the desired Taylor rate $r_t^*$ (the $\alpha_t^*$ in (4.1)) as a constant because of the assumption of the constant real interest rate. This assumption, however, does not seem appropriate for Japan, given the decline in the trend growth rate during the “bubble” period of the late 1980s to the early 1990s, shown in Figure

---

12 See Miyazawa (2010) for a survey.

13 In Taylor’s (1993) original formulation, the constant term $\alpha_t^*$ equals 1%. It is the difference between the equilibrium real interest rate, which is assumed constant at 2%, and half times the target inflation rate of 2%.
2c. That the intercept $\alpha^*$ may have declined during the period can be seen from the figure. Before the bubble, say in 1988, the 12-month inflation rate was very low, about 0.4% but the policy rate was well above zero, about 4%. In the post-bubble period, both the policy rate and the inflation rate are very low. See Figure 3 below for the behaviour of the desired rate when trend growth is factored in.

- (deviations from the Taylor rule) It is widely agreed that the BOJ under governor Yasushi Mieno set the policy rate at a very high level to quell the asset price bubble. We view this as a prolonged deviation from the Taylor rule and include a dummy variable, to be called the “Mieno dummy”. It takes a value of 1 from December 1989, when Mieno became governor, to June 1991, the month before the policy rate was cut. Another deviation seems to have occurred during the banking crisis of the second half of the 1990s. Between September 1995 and July 1998, the policy rate remained low despite improvements in inflation and output. Assuming that the BOJ refrained from raising the policy rate to help alleviate the Japanese banking crisis, we include a dummy for this period in the equation as well.

Economists at the BOJ were aware of the intercept drift due to changing real interest rates.

---

14 For example, Hayashi and Prescott (2002) document that both the TFP (total factor productivity) and the rate of return on capital declined in the early 1990s. The Taylor rule for Japan in Braun and Waki (2006) allows the equilibrium real rate to vary with the TFP growth.

15 The decline in the output gap only partially explains the post-bubble low policy rates. The output gap was 0.8% in 1988 and -2.0% in 1995. Even if the output gap coefficient in the desired Taylor rule is as high as 0.5, the decline in the desired rate explained by the output gap is about 1.4% ($= 0.5 \times (2.0\% + 0.8\%)$).

16 See, for example, a booklet for popular consumption by Okina (2013) who was a director of the BOJ’s research arm.

17 The Bank of Japan started releasing minutes of the monetary policy meetings only since March 1998 (the 3 March 1998 release is about the meeting on January 16, 1998), so it is not possible for outside observers to substantiate the claim. However, those released minutes of the early part of 1998 do include frequent mentions of the financial system. For example, the minutes of the 16 January 1998 meeting has the following passage: “...a majority of the members commented that the sufficient provision of liquidity would contribute to stabilizing the financial system and to improving household and depositor sentiment.”
For example, Okina and Shiratsuka (2002) include the trend growth rate (as measured as the 12-month growth rate of potential GDP) in their Taylor rule.\(^{18}\) We do the same here. Our specification of the Taylor rule, therefore, is that the intercept \(\alpha^*_r\) in the desired Taylor rule is an affine function of the trend growth rate as well as the Mieno (anti-bubble) and banking crisis dummies.

Table 4 reports our ML estimates. The Mieno dummy coefficient of 2.5\% in the desired Taylor rate indicates that the policy rate during the height of the bubble was well above what is prescribed by the Taylor rule. As expected, the banking crisis dummy has a negative sign — the desired policy rate would have been higher on average by 37 basis points were it not for the banking crisis. The trend growth rate has a coefficient that is close to unity (0.98) and highly significant \((t = 11.5)\). The inflation and output coefficients \((\beta^*_C\) in (4.1)) are estimated to be \((0.75, 0.07)\). Given the low persistence of inflation (to be found in the reduced-form inflation equation below), it is not surprising that the inflation coefficient is below unity. The estimated speed of adjustment per month is 14\%. The mean of the time-varying threshold inflation rate affecting the exit condition is mere 0.53\% per year.

We should note that it is crucial to include the Mieno dummy if the sample includes the bubble period because without it the inflation coefficient is very imprecisely estimated \((0.32, t = 0.5)\), with the run-up of the policy rate during the bubble period almost entirely attributed to the trend growth rate.

The desired Taylor rate \(r^*_t\) implied by the ML estimate is shown in the dotted line in Figure 3. It highlights the role of the exit condition. The desired Taylor rate \(r^*_t\), and hence the shadow Taylor rate \((\rho r^*_t + (1 - \rho) r^-_{t-1})\), turned positive in the middle of QE2. Yet the QE was not terminated until the inflation rate is slightly above zero (as shown in Table 2).

**Excess reserve supply equation (\(\theta_C\)).**

\(^{18}\) As is well known in the RBC (real business cycle) calibration literature, the trend growth rate is closely linked to the equilibrium real interest rate. For the case of the power utility \(u(C) = \frac{1}{1 - \gamma} C^{1 - \gamma}\), the long-run (log) real interest rate is an affine function of the trend growth rate: \(-\log(\beta) + \gamma g\), where \(g\) here is the long-run growth rate of output. In the case of the log utility \((\gamma = 1)\), the long-run real interest rate and the trend growth rate move one-for-one.
We have noted that the ML estimator can be obtained by regressing \( m_t \) on the constant, \( \pi_t, x_t \), and \( m_{t-1} \) on subsample Z. We have also noted earlier that QE1 looks very different from QE2 and QE3, with \( m_t \) much lower and less persistent during QE1. For this reason we drop QE1 when estimating the excess reserve supply equation. The estimates are in Table 5. Both the inflation and output coefficients pick up the expected sign. The issue of how to treat \( m \) during QE1 will be addressed in Section 8.

**Inflation and output reduced-form equations \((\theta_A)\).**

As mentioned above, the ML estimate of the reduced form can be obtained by OLS on two separate subsamples, “lagged” subsample P (i.e., those \( t \)’s with \( s_{t-1} = P \)) and “lagged” subsample Z (with \( s_{t-1} = Z \)). The BIC (Baysian information criterion) instructs us to set the lag length to one on both subsamples.\(^{19}\) We include the current values of the Mieno (anti-bubble) and the banking crisis dummies and the trend growth rate in the set of regressors in order to allow those variables to affect the intercepts of the reduced form.

Table 6 shows the estimates. First consider lagged subsample P. We exclude lagged \( m \) in order to be consistent with the model’s current assumption that \( m = 0 \) under regime P; in Section 8, when we recognize occasionally positive excess reserves, the effect of lagged \( m \) will be taken into account.

On lagged subsample P, Andrew’s (1993) sup \( F \) test finds no structural break for the

\[^{19}\text{If } n \text{ is the lag length and } K \text{ is the total number of coefficients (including the intercepts) of the bivariate system, we have } K = 2 \times (2 + 4n) \text{ for lagged subsample } Z \text{ (there are two regressors besides } (p, x, r, m): \text{ the constant and the trend growth rate). For lagged subsample } P \text{, we have } K = 2 \times (4 + 3n) \text{ because lagged } m \text{ is absent but the Mieno and banking crisis dummy are present. Let } T \text{ be the sample size and } \tilde{\varepsilon}_t \text{ be the } 2 \times 1 \text{ matrix of estimated reduced-form residuals. Given the moderate sample size, we set the maximum lag length at } n_{\text{max}} = 6 \text{ and the sample starts from } t = \text{July 1988. The information criterion to be minimized over } n = 1, 2, ..., n_{\text{max}} \text{ is}\]

\[
\log \left( \frac{1}{T} \sum_{t=1}^{T} \tilde{\varepsilon}_t \tilde{\varepsilon}_t' \right) + K \cdot C(T)/T,
\]

where \( C(T) = \log(T) \). Under the AIC (Akaike information criterion) which sets \( C(T) = 2 \), the lag length chosen is 2 for lagged subsample P and 1 for Z.
inflation equation but a structural break for the output equation occurring in March 1995. We show in Table 6 the reduced-form estimates for the two P subsamples split at March 1995. The output gap (x) equation indeed looks very different before and after the break, particularly for the lagged x and the lagged r coefficients. The output persistence measured by the lagged x coefficient is much lower before the break. The output effect of the policy rate (the lagged r coefficient) is similar in magnitude but the sign is reversed.

The monthly inflation (p) equation on lagged subsample P, with no significant structural breaks, exhibits two notable features, observable before and after the break. First, inflation persistence is non-existent, as indicated by the lagged p coefficient of about −0.1. Second, the lagged r coefficient is positive and large. The estimated value of the coefficient of 0.44 after the break means that a 1 percentage point cut in the policy rate lowers inflation by 0.44 percentage points in the next period. That is, the IR (impulse response) of a 1 percentage point cut to inflation is negative at −0.44 on impact (i.e., at horizon 1). The estimate, however, is not

---

20 In testing for structural breaks, we allow all coefficients to shift except for the Mieno and banking crisis dummies. We exclude Mieno and crisis dummies because their values are zero for many possible break dates.
statistically significant with a $t$-value of 0.8.\footnote{The positive $r_{t-1}$ coefficient may be due to the fact that $r_{t-1}$ is the average over the period of the 16th of month $t - 1$ and the 15th of month $t$. If the central bank can respond to price increases of the month by raising the policy rate in the first 15 days of the month, there will be a positive correlation between $p_t$ and $r_{t-1}$. To check this, we replaced $r_{t-1}$ by $r_{t-2}$ and found a very similar coefficient estimate.}

Turn now to lagged zero-rate subsample Z. The difference in the policy rule for excess reserves between QE1 and QE2&QE3 mean that the reduced-form coefficients during QE1 could be different. For this reason the sample excludes QE1 and combines QE2 and QE3. The regressors include $r_{t-1}$ because, although it is constant in each QE spell, it differs across spells (see Table 3). Therefore, if $r_{t-1}$ were replaced by the QE3 dummy, the lagged $r$ coefficients (of 0.49 and −0.66, both statistically insignificant) in the inflation and output equations would be scaled down by a factor of 10, with the coefficients of the other variables unchanged.

The positive lagged $m$ coefficients on lagged subsample Z imply that both inflation and output rise as excess reserves are increased. These effects are statistically significant. The coefficient of 0.40 in the output equation, for example, means that the IR of the output gap to a unit increase in $m$ (an increase by 100 percentage points) is 0.40 percentage points on impact.

\begin{align*}
  p_t &= 0.94 + 0.45 p_{t-1} - 0.12 x_{t-1} + 0.34 r_{t-1}, \\
  [1.93] & [12.1] [1.5] [7.9] \\
  x_t &= 0.023 + 0.0039 p_{t-1} + 0.99 x_{t-1} + 0.0067 r_{t-1}, \\
  [0.8] & [1.6] [187] [2.4]
\end{align*}

$t =$ March 1960,..., August 2008. Here, $p_t$ is the monthly CPI inflation rate from month $t - 1$ to $t$ in annual percentage rates, $x_t$ is the unemployment rate (not the output gap) of month $t$ in percents, and $r_t$ is the average from the 16th day of month $t$ to the 15th day of month $t+1$. The data appendix includes a documentation of the U.S. monthly data. The estimated lagged $r_{t-1}$ coefficient in the inflation equation declines as the sample becomes more recent: it is 0.31 [$t = 6.4$] if the sample starts from 1970, 0.27 [$t = 5.4$] if from 1980, and −0.08 [$t = 0.6$] if March 1995. Because the $x$ here for the U.S. data is the unemployment rate, not the output gap, the positive lagged $r$ coefficient of 0.0067 in the $x$ equation is not surprising.
6 Counter-Factual Analysis

Having identified the model, we can generate the paths of the model’s variables from some base period. Our counter-factual analysis compares the *expected value* of the variables at various horizons conditional on the actual history up to the base period to that conditional on an alternative history. The difference in history examined in this section is with respect to the monetary policy shocks including those that would bring about changes in the regime.

If the model is linear and if the only difference between the two histories is the value of one of the shocks in the base period, our counter-factual analysis reduces to the familiar IR (impulse response) analysis. Nevertheless, for nonlinear models such as ours, we find it more transparent to designate the history in terms of the model variables rather than in terms of the shock realizations. The next subsection explains the reason using a univariate example. The reader can skip the next subsection without losing continuity.

**Issues Related to Nonlinear Models: A Univariate Illustration**

For linear models, the IR analysis is well known since Sims (1980). Our model, however, is nonlinear because the dynamics depends on the regime and also because of the nonnegativity constraint on excess reserves. Several issues crop up when we extend the IR analysis from linear to nonlinear models. To illustrate, this subsection considers a possibly nonlinear univariate process whose dynamics is described by the mapping \( y_t = f(y_{t-1}, \epsilon_t) \) where \( \epsilon_t \) is an i.i.d. shock. Since there is only one shock in the model, our counter-factual analysis and the IR analysis are equivalent.

The IR proposed by Gallant, Rossi, and Tauchen (1993, hereafter GRT) compares the forecast conditional on a current history of the variable to that conditional on an alternative history that differs by a perturbation \( \delta \) for the current period. For the univariate example here, it can be stated simply and cleanly as

\[
E(y_{t+k} | y_t + \delta) - E(y_{t+k} | y_t), \quad k = 1, 2, ...
\]

(6.1)
Because the process \( \{y_t\} \) is first-order Markov, it is enough to include its current value in the conditioning information.

The definition can be stated equivalently (albeit less cleanly) in terms of the shock \( \varepsilon_t \) rather than the variable \( y_t \). The shock-based translation is via the inverse of the mapping from \( \varepsilon_t \) to \( y_t \).

Define

\[
\phi(y_t; y_{t-1}) \equiv \{ \varepsilon_t \mid y_t = f(y_{t-1}, \varepsilon_t) \}.
\]

(6.2)

This is a correspondence from \( y_t \) to \( \varepsilon_t \) conditional on lagged information \( y_{t-1} \). It can be set-valued because multiple values of \( \varepsilon_t \) can be consistent with a given value of \( y_t \). This would happen if, for example, \( y_t \) is discrete-valued or censored. By construction, the expectation conditional on both \( \varepsilon_t \) and \( y_{t-1} \), \( E(y_{t+k} | \varepsilon_t, y_{t-1}) \), is related to \( E(y_{t+k} | y_t) \) by the identity:

\[
E(y_{t+k} | y_t) = \mathbb{E}(y_{t+k} | \varepsilon_t \in \phi(y_t; y_{t-1}), y_{t-1}).
\]

(6.3)

Despite the appearance of \( y_{t-1} \) in the conditioning information, the conditional expectation does not depend on \( y_{t-1} \); the particular way in which the correspondence \( \phi \) depends on \( y_{t-1} \) is such that this is the case.\footnote{As an example, consider the linear AR1 process: \( y_t = \rho y_{t-1} + \varepsilon_t \). We have: \( E(y_{t+k} | y_t) = \rho^k y_t \), \( E(y_{t+k} | \varepsilon_t, y_{t-1}) = \rho^k \varepsilon_t + \rho^{k+1} y_{t-1} \), and \( \phi(y_t; y_{t-1}) \) is a singleton \( \{y_t - \rho y_{t-1}\} \). Setting \( \varepsilon_t = y_t - \rho y_{t-1} \), we have \( E(y_{t+k} | \varepsilon_t = y_t - \rho y_{t-1}, y_{t-1}) = \rho^k(y_t - \rho y_{t-1}) + \rho^{k+1} y_{t-1} = \rho^k y_t \). The IR by (6.1), which is also by (6.4) below, equals \( \rho^k \delta \).}

Substituting the identity (6.3) for two current realizations of the variable, \( y_t \) and \( y_t + \delta \), into (6.1), we obtain the error-based translation of GRT’s IR:

\[
\frac{\mathbb{E}(y_{t+k} | \varepsilon_t \in \phi(y_t + \delta; y_{t-1}), y_{t-1}) - \mathbb{E}(y_{t+k} | \varepsilon_t \in \phi(y_t; y_{t-1}), y_{t-1})}{\text{alternative forecast}} - \frac{\mathbb{E}(y_{t+k} | \varepsilon_t \in \phi(y_t; y_{t-1}), y_{t-1})}{\text{baseline forecast}}
\]

(6.4)

Therefore, GRT’s IR can be written as: \( E(y_{t+k} | \varepsilon_t \in \mathcal{A}, y_{t-1}) - E(y_{t+k} | \varepsilon_t \in \mathcal{B}, y_{t-1}) \) for suitably chosen \( \mathcal{A} \) and \( \mathcal{B} \). For linear models, (i) the sets \( \mathcal{A} \) and \( \mathcal{B} \) are singletons, (ii) the IR depends on the two (singleton) sets only through their difference \( \mathcal{A} - \mathcal{B} \), (iii) it is history-independent (i.e., doesn’t depend on \( y_t \) here), and (iv) it is proportional to the shock size \( \delta \). None of these features are necessarily shared by nonlinear models.
The Policy-Rate Effect

Our model is described by the mapping (4.8) where the variables are \((s_t, y_t)\) (with \(y_t \equiv (p_t, x_t, r_t, m_t)\)) and the shock vector is \((\varepsilon_t, \upsilon_t)\) where \(\varepsilon_t\) is the bivariate reduced-form shock to inflation \((p)\) and output \((x)\) while \(\upsilon_t \equiv (\upsilon_{rt}, \upsilon_{\pi t}, \upsilon_{st})\) is composed of the Taylor rule shock \((\upsilon_{rt})\), the shock to the inflation threshold \((\upsilon_{\pi t})\), and the reserve supply shock \((\upsilon_{st})\). The discrete variable of the model is \(s_t\) representing the monetary policy regime.

Start with the familiar case where the only difference between the two histories is concerning the shock to the interest rate \(\upsilon_{rt}\). Our counter-factual analysis asks: what difference would it have made if the shock were different in size. The difference is given by:

\[
E\left(y_{t+k} \mid s_t = P, \quad \left(\underline{p_t, x_t, r_t + \delta r_t, 0}, \quad y_{t-1}, ..., y_{t-10}\right)\right) \quad y_t \equiv (p_t, x_t, r_t, m_t) \text{ in the alternative history}
\]

\[
- E\left(y_{t+k} \mid s_t = P, \quad \left(\underline{p_t, x_t, r_t, 0}, \quad y_{t-1}, ..., y_{t-10}\right), \quad y = p, x, r, m.\right) \quad y_t \equiv (p_t, x_t, r_t, m_t) \text{ in the baseline history}
\]

The response profile, namely this difference at various horizons \((k)\), is the natural and transparent extension to the nonlinear model of the standard IR function of the policy-rate shock. Before commenting on the particular configuration of the current value of the variables \((s_t, y_t)\) in the baseline and alternative histories, we make three remarks about the conditional expectations forming the baseline and alternative forecasts.

1. (the conditioning information) Shifting time \(t\) forward by one period in the mapping (4.8) gives

\[
(s_{t+1}, y_{t+1}) = f_{t+1}\left((s_t, y_t), y_{t-1}, ..., y_{t-10}; (\varepsilon_{t+1}, \upsilon_{t+1}); \theta_A, \theta_B, \theta_C\right), \quad \upsilon_{t+1} \equiv (\upsilon_{rt+1}, \upsilon_{\pi t+1}, \upsilon_{st+1}).
\]

This defines the distribution of \((s_{t+k}, y_{t+k})\) conditional on \((s_t, y_t, y_{t-1}, \ldots, y_{t-10})\) for horizons \(k = 1, 2, \ldots\). This conditional distribution defines the conditional expectations. It thus suffices to include the current value of \((s, y)\) and ten lags of \(y\) in the conditioning information. In particular, there is no need to include the lagged regime \(s_{t-1}\). We also note that we are allowing future regimes to change in the conditional expectations calculations.
• (Monte Carlo integration) We compute numerically the conditional expectations by simulating a large number of sample paths generated by the mapping (6.6) and then taking the average of those simulated sample paths. In the counter-factual simulations to be reported below, 10,000 simulated paths are generated.

• (projected paths of exogenous variables) There are four exogenous variables in the system: \( \bar{r} \) (the rate paid on reserves), the banking crisis dummy (for September 1995-July 1998), the Mieno (anti-bubble) dummy (for December 1989-June 1991), and the trend growth rate (the 12-month growth rate of potential GDP). Each simulated sample path of \((s, y)\) from the base period \(t\) depends on the projected path from \(t\) on of those exogenous variables. Our counter-factual analysis, which compares two simulated sample paths, is invariant to the projected exogenous variables path with linear systems, but not so with nonlinear systems such as ours. The projected path of the exogenous variables we use for our calculations of the response profile is their actual path (with the values beyond the sample period set equal to the value at the end of the period).

Two points regarding the configuration of \((s_t, y_t)\) in the baseline and alternative forecasts in (6.5):

• (the reduced-form shocks are controlled for) Not only the history up to \(t - 1\) but also the current value of \((p_t, x_t)\) are the same in both the baseline and alternative histories; the only difference is that the policy rate \(r_t\) differs by \(\delta_r\). In terms of shocks, the reduced-form shocks \(\varepsilon_t\) are the same but the Taylor rule shock \(v_{rt}\) differs by \(\delta_r\) (see Appendix 2, particularly (A2.21), for a more formal statement). Thus the difference in the policy rate is purely due to an exogenous policy decision.

• (restrictions on \((s_t, y_t)\) for well-defined conditional expectations) Given that the common regime is \(P\), in order for the conditional expectations to be well-defined, (i) \(m_t\) (the excess reserve rate) must be 0 in both the baseline and alternative histories because of the assumption

---

24 Therefore, the expectations operator should have a subscript \(t\) (\(E_t\) rather than \(E\)). We won’t carry this sub \(t\) for notational simplicity.
(to be relaxed in Section 8) of zero excess reserve demand under P, and (ii) \( r_t > \tilde{r}_t \) in the baseline history and \( r_t + \delta_r > \tilde{r}_t \) in the alternative history because under P the lower bound is not binding.

In the next several figures, we display the estimated response profiles with error bands. The error bands are obtained as follows. Draw a parameter vector from the estimated asymptotic distribution and do the Monte Carlo integration (with 1,000 simulations given the parameter vector).\(^{25}\) Continue this until we accumulate 400 “valid” response profiles.\(^{26}\) Pick the 84 and 16 percentiles for each horizon (so the coverage rate is 68%, corresponding to one-standard error bands).

Figure 4a shows the policy-rate effect, namely the response profiles given in (6.5) for horizons \( k = 0, 1, 2, ..., 60 \). The interest-rate shock is \( \delta_r = -1 \), that is, a policy rate cut of 1 percentage point. In contrast to the linear case, the difference in conditional expectations depends not only on how the alternative history differs from the baseline but also on the baseline history itself. So the baseline period needs to be specified. In order to calculate the response profiles of the policy rate cut, however, the base period has to be May 1995 or before, when the policy rate is above 1 percent. We take the base period \( t \) to be the earliest month after the structural break,

\(^{25}\) The likelihood function is additively separable as shown in (5.1) where \( \theta_A \) is the bivariate reduced-form parameters (including the error variance-covariance matrix), \( \theta_B \) is the Taylor rule parameters, and \( \theta_C \) describes the excess reserve supply function. Consequently, if \( \tilde{\theta}_A \) is the ML estimator of \( \theta_A \), for example, and if \( \text{Avar}(\tilde{\theta}_A) \) is its asymptotic variance, a consistent estimator, \( \hat{\text{Avar}}(\tilde{\theta}_A) \), of the asymptotic variance is the inverse of \( 1/T \) times the Hessian of \( L_A(\theta_A) \) where \( T \) is the sample size. For \( \theta_B \), we draw the parameter vector by generating a random vector from \( N(\hat{\theta}_B, \frac{1}{T} \hat{\text{Avar}}(\tilde{\theta}_B)) \). We do the same for and \( \theta_C \). For \( \theta_A \), we draw the parameter vector according to the RATS manual. That is, let \( \tilde{\Sigma} \) here be the ML estimator of the \( 2 \times 2 \) variance-covariance matrix \( \Sigma \) of the bivariate error vector in the reduced form. It is simply the sample moment of the bivariate residual vector from the reduced form. We draw \( \Sigma \) from the inverse Wishart distribution with \( T\tilde{\Sigma} \) and \( T - K \) as the parameters, where \( T \) is the sample size and \( K \) is the number of regressors. Let \( \tilde{\Sigma} \) be the draw. We then draw reduced-form coefficient vector from \( N(b, \tilde{\Sigma} \otimes (TS_{XX})^{-1}) \), where \( b \) here is the estimated reduced-form coefficients and \( S_{XX} \) is the sample moment of the reduced-form regressors.

\(^{26}\) Let \( IR(i, k) \) be the \( k \)-period ahead response of variable \( i \) and let \( n \) be the horizon. For each \( i \), define \( v_{1i} = \sum_{k=1}^{\ell} (IR(i, k))^2 \) and \( v_{2i} = \sum_{k=\ell+1}^{n} (IR(i, k))^2 \) where \( \ell \) is the largest integer not exceeding 0.8\( n \). We declare the response profile “valid” if \( \max_i v_{2i}/v_{1i} \leq 0.1 \). We set \( n \) (the response horizon) to 120.
March 1995, when the policy rate, at $r_t = 2.0\%$, was comfortably above zero.

In the figure, that the rate cut is 1 percentage point can be read off from the intercept of the profile in the lower-left panel, which shows the response profile of $r$ to $r$. In the response profile for $p$, shown in the upper-left panel, the immediate response (at horizon $k = 1$) is negative, at $-0.44\%$. As mentioned in the previous section, the immediate response equals the perturbation $\delta_r$ times the lagged $r$ coefficient in the reduced-form for inflation. The immediate response does not depend on the history because the reduced form in the next period depends on the current regime. The immediate response’s wrong sign is quickly reversed in several months. The error band shows that, for all $k$, the response is not significantly different from zero. The output gap response shows that the rate cut has a strong expansionary effect, reaching a peak of about $2.4\%$ in 12 months. Because of the high initial policy rate of $2.0\%$, the system rarely switches to QE in the simulations (the average duration of the initial regime of P is about 3 years under either scenario, baseline or alternative), which explains the almost no response of $m$ as shown in the south-east panel of the figure.

The QE Effect

We turn to examine the response to changes in the excess reserve rate $m$. Since the central bank has control over $m$ only under the zero-rate regime, we set $s_t = Z$ in both the baseline and alternative histories. Given that the common regime is $Z$, for the conditional expectations to be well-defined, set $r_t = \tilde{r}_t$ in both histories. These considerations determine the configuration of $(s_t, y_t)$ in the baseline and alternative histories. The response to the QE shock $\nu_{st}$ is thus the following difference:

$$
E\left(y_{t+k} \mid s_t = Z, \left( p_t, x_t, \tilde{r}_t, m_t + \delta_m \right), y_{t-1}, ..., y_{t-10} \right)
$$

$y_t = (p_t, x_t, r_t, m_t)$ in the alternative history

$$
- E\left(y_{t+k} \mid s_t = Z, \left( p_t, x_t, \tilde{r}_t, m_t \right), y_{t-1}, ..., y_{t-10} \right), y = p_t, x_t, r_t, m_t.
$$

$y_t = (p_t, x_t, r_t, m_t)$ in the baseline history

Here, as in the case of the interest-rate shock, the response is purely policy-induced, because we are controlling for the reduced-form shock $\epsilon_t$ by requiring $(p_t, x_t)$ to be the same in both histories. The only difference between the two histories is that the QE shock $\nu_{st}$ is higher in the alternative
history by δr (see (A2.22) for the error-based translation of the two histories).

The QE effect, namely the profile of the response to m, does not depend very much on the choice of the base period t. Figure 4b shows the response profiles for the base period of February 2004 (the peak QE month) when \( m_t = 1.849 \), about 6.4 (= exp(1.849)) times required reserves.\(^{27}\) The lower-left panel shows the response profile of m to m, so its intercept at horizon \( k = 0 \) (the base period) equals the perturbation \( \delta_m \). Its size is chosen so that its ratio to the estimated standard deviation of the reserve supply shock \( v_{st} \) (which is 0.132 from Table 5) roughly equals the ratio of \(-\delta_r\) (the size of the interest-shock) to the estimated standard deviation of the policy rate shock \( v_{rt} \) (0.134 from Table 4). We have already set \( \delta_r = -1 \) percentage point, so \( \delta_m = 1.0 \).

The response profile for the output gap (x) is shown in the upper-right panel of the figure. Its immediate response (the response at \( k = 1 \)) is about 0.40% (which is the lagged m coefficient in the output equation of 0.40 shown in Table 6 times \( \delta_m = 1 \)). Because of the persistence in the output dynamics exhibited in the estimated reduced form, the response builds on the immediate response and goes up to nearly 2% in 12 months or so. For monthly inflation (p), the immediate response (at \( k = 1 \)) is greater, but the effect tapers off due to the lack of persistence. Because both output and inflation rise, regime P is more likely to occur under the alternative scenario. This is why the response of the policy rate (r) gradually rises from zero with the response of m turning negative. This also explains why the average duration from the base period of the initial regime (which is Z in both the base and alternative scenarios) is shorter under the alternative scenario with 10 months than under the base scenario with 28 months.

**What Would Have Happened if the Exit Were Delayed?**

We can conduct more interesting analysis by allowing the two histories to differ in more than one respect. To illustrate, we examine the episode of the winding-down of QE2. The data on \((s_t, m_t, r_t, p_t, \pi_t, x_t)\) during the episode are in Table 2.

The last month of QE2 is June 2006 and the normal regime P resumed in July 2006. In

\(^{27}\) Because the base period \( t \) is after the structural break date of March 1995, the estimated reduced-form parameter vector \( \widehat{\theta}_A \) used for simulating sample paths for the Monte Carlo integration comes from the reduced-form estimate for the post-break period (the middle panel in Table 6).
terms of our model, the combination of the inflation and output shocks \((\epsilon_t)\) and the policy shocks \((v_t \equiv (v_{rt}, v_{\pi t}, v_{st}))\) for July 2006 was such that the outcome of the mapping (4.8) was, unlike in the previous month, \(s_t = P\). What difference would have emerged if QE2 were allowed to continue, namely if the reduced-form shocks \(\epsilon_t\) for July 2006 were the same but the configuration of the policy shocks \((v_{rt}, v_{\pi t}, v_{st})\) were different enough for the central bank to choose the different regime of \(P\)?

We can answer the question by setting \(t = July 2006\) (when the regime was \(s_t = P\)) and taking the alternative history to be one with \(s_t = Z\). The difference we calculate, then, is

\[
E(y_{t+k} | s_t = Z, (p_t, x_t, \bar{r}_t, m_t^0), y_{t-1}, ..., y_{t-10}) - E(y_{t+k} | s_t = P, (p_t, x_t, r_t, 0), y_{t-1}, ..., y_{t-10}),
\]

counter-factual history  observed history in July 2006

(6.8)

where \(m_t^0\) is the level of \(m_t\) that can be expected given the history leading up to \((p_t, x_t)\) and given the current regime is \(s_t = Z\) (so \(m_t\) is supply-determined). It can be written as

\[
m_t^0 \equiv E[ \max[m_{st}, 0] | p_t, x_t, y_{t-1}, ..., y_{t-10}] = E_{\sigma_m}[\max[m_{st}, 0] | \pi_t, x_t, m_{t-1}]
\]

with \(m_{st}\) given by (4.7).

Thus, the perturbation occurs to not just one but three variables: \(r_t, m_t\), and \(s_t\).

The estimate of this \(m_t^0\) for \(t = July 2006\) is 0.45, which is about 1.6 \((= \exp(0.45))\) times required reserves, about a quarter of the ratio (of 6.4) observed at the peak QE month of February 2002. The estimated response profiles of the difference (6.8) for \(y = p, x, r, m\) is in Figure 4c. The perturbations to \(m\) of \(\delta_m = 0.45\) and to \(r\) of \(\delta_r = -0.26\) (\(r_t = 0.26\%\) and \(\bar{r}_t = 0\%\) in July 2006) can be read off from the intercepts in the two lower panels. Surprisingly, despite the increase in \(m\) and the cut in the policy rate, both inflation and output decline. Continuing QE2 would have been contractionary.

---

\(28\) This conditional expectation can be computed analytically by one of the standard Tobit formulas. Consider the Tobit model \(y = \max[x'\beta + u, c]\) where \(u \sim N(0, \sigma^2)\). We have: \(E(y|x) = [1 - \Phi(v)] \times [x'\beta + \sigma \lambda(v)] + \Phi(v)c\), where \(v \equiv (c - x'\beta)/\sigma\) and \(\lambda(v) \equiv \phi(v)/[1 - \Phi(v)]\). Here, \(\phi\) and \(\Phi\) are the pdf and cdf of the standard normal distribution.
To see why, decompose the (overall) difference (6.8) as the sum of three differences:

\[
(6.8) = E\left(y_{t+k} \mid s_t = Z, (p_t, x_t, \bar{r}_t, m^c_t), \ldots \right) - E\left(y_{t+k} \mid s_t = Z, (p_t, x_t, \bar{r}_t, 0), \ldots \right)
\]

"QE effect"

\[
+ E\left(y_{t+k} \mid s_t = Z, (p_t, x_t, 0, \ldots) \right) - \lim_{r \downarrow r_t} E\left(y_{t+k} \mid s_t = P, (p_t, x_t, r, 0), \ldots \right)
\]

"transitional effect from P to Z"

\[
+ \lim_{r \downarrow r_t} E\left(y_{t+k} \mid s_t = P, (p_t, x_t, r, 0), \ldots \right) - E\left(y_{t+k} \mid s_t = P, (p_t, x_t, r_t, 0), \ldots \right)
\]

"rate-cut effect"

The culprit is the second difference which can be aptly called the “transitional effect”. Its profile, shown in Appendix Figure 2, is very similar to the overall profile in Figure 4c. As we know from Figure 4b, the first component (the QE effect) is expansionary, which means that the third component (the rate-cut effect) for the same base period is contractionary in spite of the decline in the policy rate from \(r_t = 0.26\%\) to (arbitrarily above) \(\bar{r}_t = 0\%). This is because lowering the rate from an already very low level makes it more likely that the regime switches from P to Z in the future with all the contractionary effect of the transitional effect from P to Z. That the rate-cut effect (the third component) is almost a mirror image of the QE effect (the first component) is shown in Appendix Figure 3.

Mechanically, the source of the transitional effect is that the reduced-form coefficients depend on the regime. Appendix 3 provides an analytical expression that links the reduced-form coefficients to the transitional effect for \((p, x)\). It shows that the contractionary transitional effect from P to Z is primarily due to the lower values of the reduced-form intercepts under Z.

**Would Earlier Exits Have Been Expansionary?**

A question arises: if delaying the exit in July 2006 would have been contractionary, would it have been better to exit earlier? We can answer this question by considering the opposite of (6.8) for the base period \(t\) before July 2006 when the excess reserve rate \(m_t\) was greater. That is, take Z, not P, as the baseline regime and take P, not Z, as the counter-factual alternative regime. So the
difference we calculate would be

$$\lim_{r \downarrow r_t} \mathbb{E}(y_{t+k} \mid s_t = P_r(p_t, x_t, r, 0), y_{t-1}, ..., y_{t-10}) - \mathbb{E}(y_{t+k} \mid s_t = Z_r(p_t, x_t, \tilde{r}_t, m_t), y_{t-1}, ..., y_{t-10})$$

(6.11)

for any of the Z months preceding July 2006. This difference can be decomposed as

$$\begin{align*}
(6.11) &= \lim_{r \downarrow r_t} \mathbb{E}(y_{t+k} \mid s_t = P_r(p_t, x_t, r, 0), ...) - \mathbb{E}(y_{t+k} \mid s_t = Z_r(p_t, x_t, \tilde{r}_t, 0), ...) \\
&= \left[ \lim_{r \downarrow r_t} \mathbb{E}(y_{t+k} \mid s_t = P_r(p_t, x_t, r, 0), ...) - \mathbb{E}(y_{t+k} \mid s_t = Z_r(p_t, x_t, \tilde{r}_t, 0), ...) \right] \\
&\quad + \left[ \mathbb{E}(y_{t+k} \mid s_t = Z_r(p_t, x_t, \tilde{r}_t, 0), ...) \mathbb{E}(y_{t+k} \mid s_t = Z_r(p_t, x_t, \tilde{r}_t, m_t), ...) \right] \\
&\quad \text{“transitional effect from Z to P”} \\
&\quad + \text{“negative of the QE effect”}
\end{align*}$$

(6.12)

There are two components operating in the opposite directions. The first component is expansionary because it is the negative of the transitional effect from P to Z which, as just seen, is contractionary. The other component, which is due to the decline in the excess reserve rate from $m_t$ all the way to zero, is contractionary. Whether the overall difference (6.11) is positive or not (namely, whether ending QE would have been expansionary or not) depends on the strength of the second component which, in turn, depends on the size of $m_t$. If $m_t$ is not large enough, the first component dominates and the profiles of inflation and output responses would be the opposite of those in Figure 4c. This is indeed the case for $t = June 2006$ (with $m_t = 0.46$ as shown in Table 2), May 2006 (with $m_t = 0.55$) and April 2006 ($m_t = 1.0$ or the actual-to-required reserve ratio of 2.7), but not for March 2006 with $m_t = 1.51$ or with the actual-to-required reserve ratio of 4.5. Exiting from QE2 in March 2006 and hence reducing $m$ from 1.51 to zero would have been contractionary.
The paper’s two major findings — that the QE effect exists and that the transitional effect from the zero-rate to the normal regime is contractionary — could be controversial. This section explores possibilities that might explain those findings.

**Why Do Excess Reserves Matter?**

The prevailing view about excess reserves, expounded by Eggertson and Woodford (2003), is that they don’t matter when the nominal rates are close to the lower bound. Why, then, does the excess reserve rate \( m \) show up with a significant coefficient in the reduced form for inflation \( (p) \) and the output gap \( (x) \) on QE months? Here we examine three possible explanations. One is its effect on the long-term interest rates through reserve-financed changes in the central bank’s asset size and its maturity structure. Another is the signalling effect on other asset prices. Yet another is possible balance-sheet adjustments by commercial banks prompted by the capital requirement. We take up each of them in turn.

**Long-Term Interest Rates**

To examine the transmission channel through the long-term interest rates, two issues must be addressed. First, did QE lower the long-term interest rates? Second, if so, did the lower interest rates raise output and inflation? Long-term bond purchases by the central bank could lower the long-term interest rates either by compressing the term premium or by the signalling effect that lower expected future short-term interest rates. Recent event studies surveyed by Woodford (2012), particularly the work by Bauer and Rudebusch (2014), attribute an important role to the signalling effect associated with the Fed’s LSAP (large-scale asset purchases) announcements. For Japan, the issue is the extent of the signalling effect because the reserve-financed assets growth is mostly through short-term government bonds. The evidence reported in Ueda (2012) is that announcements of reserve increases during QE2 had no effect on the long-term interest rates. Even if an increase in reserves lowers the long-term interest rates though the signalling effect, the excess reserve rate \( m \) would not have entered the reduced-form equation for inflation and output if it had no macroeconomic effect. There are relatively few studies on this issue. The
DSGE model of Chen, Curdia, and Ferrero (2012) implies that the Fed’s second LSAP increased GDP growth by only a third of a percentage point, with no effect on inflation.

We have enough monthly observations to evaluate this transmission channel without resorting to the event study technique. We expand our SVAR to include the spread between the 10-year government bond yield and the policy rate. If $z_t$ denotes the additional variable (which here is the spread) for period $t$, the two reduced-form equations now have $z_{t-1}$ as the additional regressor, and there is an additional equation, placed after the policy variables block, that has $z_t$ as the dependent variable and $(p_t, x_t, r_t, m_t, z_{t-1})$ (in addition to the exogenous variables) as regressors. The first numerical row of Table 7 extracts relevant coefficients estimates on the 112 observations consisting of QE2 (March 2001 - June 2006) and QE3 (December 2008 - December 2012). It shows that the long-term interest rate channel is almost non-existent. To see this, look at the $z_t$ (the spread) equation first. The coefficient of $m_{t-1}$ is $-0.03$, implying that a unit increase (an increase by 100 percentage point) in the excess reserve rate contemporaneously lowers the spread only by 3 annual basis points. Next look at the reduced form. Take the output gap, for example. The estimated immediate response to the 100 percentage point increase in $m$ is to lower the output gap by an insignificant amount ($0.26 \times 0.03$ percentage points). It is noteworthy that lagged $m$ coefficients in the reduced form are very similar, in magnitude and in significance, to those in Table 6 where $z_{t-1}$ is not included.

**Other Asset Prices**

The QE’s signalling effect could have macroeconomic effects through asset prices other than the long-term interest rates. Here we examine the exchange rates and Tobin’s $q$. The second numerical row of Table 7 is an extract from the SVAR system with the Yen/Dollar exchange rate. With no significant coefficients of the relevant variables, the exchange-rate channel is non-existent. On the other hand, as the third row of the Table shows, the channel through Tobin’s $q$ may have been in operation. The effect on $q$ of current $m$ is significant with a $t$-value of 1.99. The lagged $q$ coefficients in the reduced form are positive and, for output, the $t$-value is above 1, at 1.26. It is possible that lagged $q$ coefficient has a higher $t$-value if $q$ is better measured. As Honda (2014) notes, the $q$ channel is consistent with the fact that GDP share of investment
increased substantially during QE2.

**The Capital Requirement**

There is another explanation, due to Ennis and Wolman (2015), which has to do with the capital requirement imposed on commercial banks. If the government bonds purchased by the central bank are initially owned by commercial banks, then any expansion of bank reserves are matched by a decrease in securities owned by commercial banks, so the open market operation does not increase the size of banks’ assets. To the extent that bonds purchased by the central bank are initially owned by non-banks, the assets held by commercial banks increase. Therefore, as reserves continue to expand, at some point the capital requirement will become binding. One possibility, of course, is that commercial banks will reduce lending growth, which is contractionary. Another possibility, pointed out by Ennis and Wolman (2015), is that banks might attempt to shed assets and liabilities by inducing depositors to withdraw currency and the public decides to spend the extra cash. Indeed, in Ennis’s (2014) flexible-price general equilibrium model with an explicit modelling of the banking sector, an increase in reserves engineered by open market operations brings about a proportionate increase in the price level.\(^{29}\) This is because bank loans are demand-determined and the supply curve of bank capital is vertical in his model.

To corroborate the Ennis-Wolman conjecture, the last row of Table 7 has the the growth rate of bank loans as the additional variable to the SVAR. The relevant coefficients are all positive, which is consistent with the premise of Ennis-Wolman conjecture that the growth of reserves at least was not at the expense of loan growth.

**Can There be a Policy-Induced Exit That is Expansionary?**

There is a well-known model of an exit from the liquidity trap by Krugman (1998) and Eggertson and Woodford (2003). The exit in that model occurs when the real interest rate turns from

\(^{29}\) See Corollary 3.1 and its proof in Ennis (2014). A detailed model of the banking sector that has an explicit formulation of the liquidity service of reserves in Bianchi and Biggio (2014) shows that an increase in reserves past the point where the marginal liquidity service falls to zero would bring about balance-sheet adjustments due to the capital requirement. However, they do not examine its possible macroeconomic effect.
negative to positive. Can there be a model in which the exit from the liquidity trap is engineered by a judicious choice of policy shocks? Such a model is presented in Appendix 5:. It is a minor variation of the exit model of Eggertson and Woodford (2003). The role played by the real interest rate in their model is played by the monetary policy shock $\nu_{rt}$ in the example of Appendix 5:. As first noted by Benhabib, Schmitt-Grohe, and Uribe (2001), the “aggressive” Taylor rule with the inflation coefficient that is greater than unity produces two equilibria, one of which is the liquidity trap. In our example, if monetary policy shock is positive, the exit condition eliminates the “good” equilibrium with a positive nominal interest rate, sending the economy to the liquidity trap. When the monetary policy shock is reset to zero, the good equilibrium re-emerges.

Two caveats are in order about this example. First, inflation, output, and the policy rate are determined simultaneously, in contradiction of the assumption in our SVAR model that inflation and output are pre-determined. Second, the monetary policy shock $\nu_{rt}$, which is persistent in the example, is i.i.d. in the SVAR model. We have not been able to find an example of a policy-induced exit that overcomes these challenges.
8 Robustness and Extensions

In this section, we examine how the inflation and output responses shown in Figure 4a-4c are affected to various changes to the model. It will be shown that: (i) allowing for two QE types makes very little difference, (ii) turning the demand for excess reserves on dampens the interest-rate effect shown in Figure 4b, and (iii) changing the measure of potential GDP to HP (Hodrick-Prescott) filtered GDP brings about the price puzzle.

**HP-Filtered GDP as Potential GDP**

So far, the measure of potential GDP that underlies the output gap and the trend growth rate has been the official estimate from the Cabinet Office. We now change the measure to the HP-filtered GDP which, as shown in Figure 2b, tracks actual GDP more closely than the Cabinet Office measure. For example, the output gap has been mostly positive since July 2011.

Figure 5a-5c show the monthly inflation \( p \) and output \( x \) responses with the alternative measure of potential GDP. To save space, the response profiles of the policy rate \( r \) and the excess reserve rate \( m \) are not shown because they look very similar to those in Figure 4. Of the three major conclusions stated in the introduction, two of them hold up: QE is expansionary and the exit from QE2 was expansionary. The conclusion about the effect of policy rate cuts does not fare so well, however. Recall from Figure 4b that the response of \( p \) to a 1 percentage point rate cut is, although negative initially, positive for most of the rest of the horizon and that the output response is positive and strong. The response profile for \( p \) in Figure 5b exhibits the price puzzle, with the inflation response never recovering from the initial negative effect. The output response is about a half in size. The error bands are generally wider.

**Excluding the Trend Growth Rate from the System**

If we exclude the trend growth rate from both the reduced form shown in Table 6 and the Taylor rule in Table 4, the model becomes the one studied in Hayashi and Koeda (2014). The response profiles shown in Figure 4 remain more or less the same except for Figure 4b about the interest rate cut. The price puzzle emerges and output shows virtually no response.
The reason for this is well understood since Sims (1992). If there is a variable (the trend growth rate in the present case) that the central bank responds to but is not included in the Taylor rule, then what the econometrician regards as the monetary policy shock will include not only the true policy shock but also the effect of this missing variable. If this variable is also missing in the inflation and output reduced form, then the response to the incorrectly identified policy shock will be contaminated by the effect of the missing variable. In the case of a rate cut, the contaminated policy shock contains not only a genuine unexpected decrease in the policy rate but also a decline in the trend growth rate. For output, the expansionary effect of a rate cut is offset by the contractionary effect of a decline in trend growth. This explains the virtual non-response of output to a rate cut found in Hayashi and Koeda (2014).

Turning Excess Reserve Demand On

In all the simulations underlying the Monte Carlo integration, we turned the demand for excess reserves off by setting \( m \) to zero under regime P. We now relax this assumption. It entails three changes. First, replace the zero excess reserve under P in (4.6) by \( \max[m_{dt}, 0] \) where \( m_{dt} \) is the demand for excess reserves to be specified below. Second, include lagged \( m \) in the reduced-form equations for lagged subsample P. The upper panel of Table 8 has the reduced-form estimates for the post break period from March 1995. The lagged \( m \) coefficient comes out with a negative sign in both the \( p \) and \( x \) equations. Third, the definition of interest rate effect in (6.5) and the transitional effect in (6.8) needs to be modified as follows: In (6.5), replace the zero for \( m_{t} \) in the alternative history by \( \mu_{t}^{(a)} \) (the expected value of \( \max[m_{dt}, 0] \) given the history up to \( r_{t} + \delta_{r} \)). Likewise, replace the zero for \( m_{t} \) in the baseline history by \( \mu_{t}^{(b)} \) (the expected value of \( \max[m_{dt}, 0] \) given the history up to \( r_{t} \)). Similarly in (6.8), replace the zero for \( m_{t} \) in both the baseline and alternative histories by \( \mu_{t}^{(b)} \) (the expected value given the history up to \( \tilde{r}_{t} \)).

The specification of \( m_{dt} \) we consider relates the excess reserve demand to the current values of \( \pi \) (the 12-month inflation rate), \( x \) (the output gap), \( r \) (the policy rate) and the lagged value of \( m \). The equation is to be estimated on the subsample in which \( m \) is demand-determined. There is no need to correct for regime endogeneity because the excess reserve demand shock is independent of the regime. The estimation method is Tobit because of the censoring in \( \max[m_{dt}, 0] \).
We argued in Section 3 that \( m \) was supply-determined during QE2 and QE3. Regarding QE1, based on our reading of the summary of discussions at the BOJ policy board meetings, we assume that \( m \) is demand-determined during QE1.\(^{30}\) Thus the subsample for the excess reserve demand equation consists of those months under regime P between January 1988 and December 2012 (170 months) and QE1 (17 months).\(^{31}\) We define the limit observations as the months for which \( m < 0.5\% \). There are 141 such months.\(^{32}\) The estimated equation is (\( t \)-values in brackets)\(^{33}\)

\[
\begin{align*}
  m_{dt} &= -0.005 + 0.011 \pi_t - 0.015 x_t - 0.12 r_t + 0.60 m_{d,t-1} + 1.01 \text{GULF}_{t,} \\
  &\quad [-0.2] [0.5] [-2.6] [-2.4] [4.4] [2.7]
\end{align*}
\]

estimated standard deviation of the error = 0.053 (s.e. = 0.0057),

sample size = 187, number of limit observations = 141.

The last regressor, GULF\(_t\), is a Gulf war dummy for February to April 1991.\(^{34}\) The output coefficient is negative, perhaps because commercial banks desire excess reserves in recessions.

The estimated error size (measured by its standard deviation) of 0.053 should be compared to the

---

\(^{30}\) In almost all the board meetings during QE1, one board member proposed to increase the current account balance far beyond what is required to guide the interbank rate to zero. The proposal was invariably voted down.

\(^{31}\) Excluding the 17 QE1 months from the sample produces very similar estimates.

\(^{32}\) Recall that we have set \( m_t = 0 \) for months between QE2 and QE3 (except the Lehman crisis months of September to November 2008), on the ground that banks postponed re-entry to the interbank market and held on to excess reserves. So those months, indicated by the thin bars in Figure 2a, are limit observations.

\(^{33}\) The regime is P in July 2006, but the previous month is the last month of QE2 when \( m \) is far above 0. We assume that the excess reserve demand in that previous month is zero. So \( m_{d,t-1} = 0 \) for \( t = \text{July 2006} \).

\(^{34}\) The value of \( m \) was about 2% in February, 5% in March, and 1% in April 1991. We include the Gulf dummy because we suspect there was some technical reason for excess reserves. At that time, there was a huge increase in the deposit by the Japanese treasury at the Bank of Japan. Most of it was for the payment of 13 billion dollars by the Japanese government to the U.S to help defray the cost of the Gulf war (which ended in February 1991). The output gap then was well above 2%, the policy rate was above 8%, and the financial system was apparently sound. There was no reason for commercial banks to hold excess reserves and the desired \( m \) would have been well below zero.
average fitted value of $m_{dt}$ of about $-0.25$ (banks on average would have liked to hold only 75% of required reserves). So $m_t$ under $P$, which is $\max[m_{dt}, 0]$, is positive only occasionally.

When the excess reserve demand is turned on, only the interest rate effect, displayed in Figure 6, is affected noticeably. As in Figure 4b, the initial regime, which is $P$ in both the baseline and alternative scenarios, lasts for about 3 years. During those years, $m$ is positive occasionally, which is contractionary because the lagged $m$ coefficient, as shown in Table 8, is negative in both the inflation and output equations under $P$. The contractionary effect is greater under the alternative scenario because the lower policy rate increases $m$ when it is positive. Thus the response of $p$ and $x$ is dampened.

### Allowing for Two QE Types

Finally, we extend the model to allow for two QE types, while the excess reserve demand is kept on. The zero-rate/QE regime $Z$ is now composed of two sub-regimes. Under the “strong” QE, as in QE2&QE3 and labeled “S”, the policy rate is zero and $m$ is determined by the excess reserve supply equation (4.7). Under the “weak” QE, as in QE1 and labeled “W”, the policy rate is zero but $m$ is set by demand. Thus the censored Taylor rule (4.4) remains valid with $Z = S, W$, but the equation determining $m_t$, (4.6), is now

$$m_t = \begin{cases} 
\max[m_{dt}, 0], & \text{if } s_t = P, W \\
\max[m_{st}, 0], & \text{if } s_t = S.
\end{cases} \quad (4.6')$$

Regarding the regime evolution (4.5), we assume that the central bank chooses between “weak” and “strong” QEs randomly, with probability $q$ for “weak” QE (“W”) and $1 - q$ for
“strong” QE (“S”). That is, (4.5) is modified as

\[
\text{If } s_{t-1} = P, \quad s_t = \begin{cases} 
P & \text{if } \rho_t r_t^* + (1 - \rho_t) r_{t-1}^* + v_{rt} > \bar{r}_t, \\
S & \text{with probability } 1 - q, \\
W & \text{with probability } q.
\end{cases}
\]

\[
\text{If } s_{t-1} = Z, \quad s_t = \begin{cases} 
P & \text{if } \rho_t r_t^* + (1 - \rho_t) r_{t-1}^* + v_{rt} > \bar{r}_t, \\
Z & \text{otherwise, } Z = S, W.
\end{cases}
\]

\[
(4.5')
\]

Thus we do not allow for the regime to change from S to W or from W to S; if the previous regime is S, for example, then the current regime is either P or S. In the response calculations below, we set \( q = 1/3 \). If we set \( q = 0 \), this model reduces to the one studied in the preceding subsection, with only one QE type and with the excess reserve demand turned on.

The last piece of the model is the reduced form under W, which needs to be estimated on lagged subsample W (those \( t \)'s for which \( s_{t-1} = W \) or \( t - 1 \) is in QE1). QE1 has only 17 observations. The shortness of the sample forces us to impose two restrictions on the reduced form. First, because \( r \) is constant (at 0) during QE1, the lagged \( r \) coefficient cannot be identified. We constrain the coefficient to be zero. Second, there is not much variation in the trend growth rate \( g \) during QE1, which creates near multi-collinearity between the constant and \( g \). We subsume the effect of trend growth rate in the constant by dropping \( g \) from the reduced form.\(^{35}\)

The lower panel of Table 8 has the estimates. Unlike the reduced form estimated on lagged subsample Z (consisting of QE2&QE3) in Table 6, the lagged \( m \) coefficient in the inflation equation is negative.

Allowing for two QE types makes so little difference that the response profiles are not shown here. Figure 4a and 4c remain virtually unaffected. The interest-rate effect looks similar to that in Figure 6, which is for the case of one QE type and the active excess reserve demand.

\(^{35}\) One way of avoiding those restrictions is to assume the reduced form is the same under W and P. But this amounts to assuming that the exit condition had no effect during QE1.
9 Conclusions

We have constructed a regime-switching SVAR in which the regime is determined by the central bank responding to economic conditions. The model was used to study the dynamic effect of not only changes in the policy rate and the reserve supply but also changes in the regime chosen by the central bank. Our impulse response analysis yields three major conclusions.

- Consistent with the existing literature, we find that an increase in the reserve supply under QE raises output and inflation.

- However, there is an entry cost to QE. That is, the effect of entering QE with no significant increase in the reserve supply is contractionary. If the central bank wishes to raise inflation and output by entering QE, it has to aggressively raise the reserve supply upon entry. The flip side of the entry cost is an exit bonus that exiting from QE is expansionary if the reserve supply at the time of the exit is not too large. Our evidence indicates that the critical level of the actual-to-required reserve ratio below which exiting from QE is expansionary is somewhere between 3 and 4.5.

The paper was able to derive all these results without a structural model of the inflation and output dynamics. There are obvious caveats that come with reduced-form approaches such as ours. First, the paper does not say why QE is expansionary or why exiting from QE can be expansionary. Second, the paper's model cannot be used for predicting the effect of policies not considered in the paper, e.g., a more aggressive QE with larger coefficients in the excess reserve supply equation or an exit from the zero-rate regime by raising the interest rate paid on reserves (as the Fed chose to do in the fall of 2015). On the plus side, much as the VAR impulse response analysis since Sims (1980) interacted with the macro modelling efforts, this paper has produced a set of stylized facts that macro theorists should strive to match.

Appendix 1  Data Description

This appendix describes how the variables used in the paper — \( p \) (monthly inflation), \( \pi \) (12-month inflation), \( x \) (output gap), \( r \) (the policy rate), \( \tilde{r} \) (the interest rate paid on reserves), and \( m \) (the excess reserve rate) — are derived from various data sources.

**Monthly and Twelve-Month Inflation Rates (\( p \) and \( \pi \))**

The monthly series on the monthly inflation rate (appearing in the inflation and output reduced-form) and the 12-month inflation rate (in the Taylor rule and the excess reserve supply equation) are constructed from the CPI (consumer price index). The Japanese CPI is compiled by the Ministry of Internal Affairs and Communications of the Japanese government. The overall CPI and its various subindexes can be downloaded from the portal site of official statistics of Japan called "e-Stat". The URL for the CPI is http://www.e-stat.go.jp/SG1/estat/List.do?bid=00000103702&cycode=0. This page lists a number of links to CSV files. One of them, http://www.e-stat.go.jp/SG1/estat/Csvdl.do?sinfid=000011288575 has the “core” CPI (CPI excluding fresh food), the “core-core” CPI (CPI excluding food and energy), and other components from January 1970. They are seasonally unadjusted series and combine different base years from January 1970. For how the Ministry combines different base years, see Section III-6 of the document (in Japanese) downloadable from http://www.stat.go.jp/data/cpi/2010/kaisetsu/index.htm#p3. Briefly, to combine base years of 2005 and 2010, say, the Ministry multiplies one of the series by a factor called the “link factor” whose value is such that the two series agree on the average of monthly values for the year 2005.

Twelve-month inflation rates constructed from the (seasonally unadjusted) “core” CPI and the “core-core” CPI are shown in Appendix Figure 1. The two humps for 1989 and 1997 are due to the increases in the consumption tax. The two inflation rates behave similarly, except for the period November 2007 - May 2009.

The above URL has another CSV file, whose link is http://www.e-stat.go.jp/SG1/estat/Csvdl.do?sinfid=000011288581, has seasonally adjusted series for various subindexes (including the “core-core” CPI), but only from January 2005. As explained below, we use the “core-core” CPI between November 2007 and May 2009 that is seasonally adjusted, along with the seasonally unadjusted “core” CPI, in order to construct \( p \) (monthly inflation) and \( \pi \) (12-month inflation). The construction involves three steps.

**Adjustment for Consumption Tax Hikes.** The consumption tax rate rose from 0% to 3% in April 1989 and to 5% in April 1997. We compute the 12-month inflation rate from the seasonally unadjusted index (as the log difference between the current value of the index and the value 12 months ago) and subtract 1.2% for \( t = \) April 1989,..., March 1990 (to remove the effect of the April 1989 tax hike) and 1.5% for \( t = \) April 1997,..., March 1998 (to remove the effect of the April 1997 tax hike). These two numbers (1.2% and 1.5%) are taken from Price Report (various years) by the Economic Planning Agency of the Japanese government (which became a part of the Cabinet Office). We then calculate the index so that its implied 12-month inflation agrees with the tax-adjusted 12-month inflation.

**Seasonal Adjustment.** We apply the U.S. Census X12-ARIMA method to the seasonally unadjusted (but consumption tax-adjusted) “core” index from January 1987 through December 2012 (26 years). The Census’s program can be downloaded from: https://www.census.gov/srd/www/winx12/winx12_down.html
The specification for the seasonal adjustment is the same as the one used by the Ministry (of Internal Affairs and Communications of the Japanese government) for seasonally adjust various CPI subindexes mentioned above. Their spec file for the Census’s X12-ARIMA program is available from http://www.stat.go.jp/data/cpi/2010/kaisetsu/pdf/3-7.pdf. For example, the ARIMA order is \((0, 1, 1)\). There is no adjustment for the holiday effect.

**Adjustment for the 2007-2008 Energy Price Swing.** Let \(CPI_{1t}\) be the seasonally adjusted “core” CPI obtained from this operation for \(t = \text{January 1970}, \ldots, \text{December 2012}\). Let \(CPI_{2t}\) be the seasonally adjusted “core-core” CPI for \(t = \text{January 2005}, \ldots, \text{December 2012}\) that is directly available from the above CSV file. Our CPI measure (call it \(CPI\)) is \(CPI_{1t}\), except that we switch from \(CPI_{1t}\) to \(CPI_{2t}\) between November 2007 and May 2009 to remove the large movement in the energy component of the “core” CPI. More precisely,

\[
CPI_t = \begin{cases} 
CPI_{1t} & \text{for } t = \text{January 1970}, \ldots, \text{October 2007}, \\
CPI_{t-1} \times \frac{CPI_{2t}}{CPI_{1t-1}} & \text{for } t = \text{November 2007}, \ldots, \text{May 2009}, \\
CPI_{t-1} \times \frac{CPI_{1t}}{CPI_{1t-1}} & \text{for } t = \text{June 2009}, \ldots, \text{December 2012}.
\end{cases}
\]  

(A1.1)

That is, the “core” CPI (the CPI excluding fresh food) monthly inflation rate is set equal to that given by the “core-core” CPI (the CPI excluding food and energy) for those months. This is the only period during which the two CPI measures give substantially different inflation rates, see Appendix Figure 1.

Finally, the monthly inflation rate for month \(t\), \(p_t\), is calculated as

\[
p_t \equiv 1200 \times [\log(CPI_t) - \log(CPI_{t-1})].
\]  

(A1.2)

The 12-month inflation rate for month \(t\), \(\pi_t\), is

\[
\pi_t \equiv 100 \times [\log(CPI_t) - \log(CPI_{t-12})].
\]  

(A1.3)

**Excess Reserve Rate \((m)\)**

Monthly series on actual and required reserves are available from September 1959. The source is the BOJ’s portal site http://www.stat-search.boj.or.jp/index_en.html/. The value for month \(t\) is defined as the average of daily balances over the reserve maintenance period of the 16th day of month \(t\) to the 15th day of month \(t + 1\). We define the excess reserve rate for month \(t\) \((m_t)\) as

\[
m_t \equiv [\log(\text{actual reserve balance for month } t) - \log(\text{required reserve balance for month } t)].
\]  

(A1.4)

We make two changes on the series. First, as was argued in Section 3, observed reserves after QE2 (which ends June 2006) and before the Lehman crisis of September 2008 do not seem to represent demand. For this reason we set \(m_t = 0\) for \(t = \text{July 2006}, \ldots, \text{August 2008}\). Second, there is a Y2K spike in \(m\) for \(t = \text{December 1999}\) (which is for the reserve maintenance period of December 16, 1999 through January 15, 2000). We remove this spike by the average of \(m\) over the QE1 months (March 1999 - July 2000) excluding December 1999.

**Interest Rate paid on Reserves \((\bar{r})\)**

\(\bar{r}_t\) is 0% until October 2008 and 0.1% since November 2008.
The Policy Rate ($r$)
We obtained daily data on the uncollateralized overnight “Call” rate (the Japanese equivalent of the U.S. Federal Funds rate) since the inception of the market (which is July 1985) from Nikkei (a data vendor maintained by a subsidiary of Nihon Keizai Shinbun (the Japan Economic Daily)). The policy rate for month $t$, $r_t$, for $t = \text{August 1985}, \ldots, \text{December 2012}$ is the average of the daily values over the reserve maintenance period of the 16th of month $t$ to the 15th of month $t + 1$.

In Section 3 of the text, we defined the zero-rate period as months for which the net policy rate $r_t - \bar{r}_t$ is less than 5 basis points. We ignore variations within the 5 basis points by setting $r_t - \bar{r}_t = 0$ for the zero-rate periods.

Monthly Output Gap ($x$)
The Three Series. Three quarterly series go into our monthly output gap construction: (i) quarterly seasonally adjusted real GDP (from the National Income Accounts (NIA), compiled by the Cabinet Office of the Japanese government), (ii) the monthly “all-industry activity index” (compiled by the Ministry of Economy, Trade, and Industry of the Japanese government (METI) available from January 1988), and (iii) the quarterly GDP gap estimate by the Cabinet Office of the Japanese government. We first provide a description of those series along with their sources.

(i) Quarterly NIA GDP

Japanese NIA in general. The Japanese national accounts adopted the chain-linking method in 2004. Quarterly chain-linked real GDP series (seasonally-adjusted) are available from the Cabinet Office. The relevant homepage is

Quarterly GDP from 1994:Q1 (GDP1). The current quarterly estimates are continuously revised by the Cabinet Office. We used the “Quarterly Estimates of GDP Jan.-Mar. 2014 (The Second Preliminary)(Benchmark year=2005)”, released on June 9, 2014 and available from the above homepage. The CSV file holding this series is:
The latest quarter is 2014:Q1 (the first quarter of 2014). For later reference, call this series “GDP1”. The series goes back only to 1994:Q1.

Quarterly GDP from 1980:Q1 (GDP2). Recently, the Cabinet Office released the chain-linked GDP series (for the same benchmark year of 2005) since 1980. The homepage from which this series can be downloaded is
http://www.esri.cao.go.jp/jp/sna/sonota/kan-i/kan-i_top.html, which unfortunately is in Japanese. The URL for the Excel file holding this series is
The URL for the documentation (in Japanese) is
This series, call it “GDP2”, is from 1980:Q1 to the 1995:Q1.

Linking GDP1 and GDP2. Because the seasonal adjustment underlying the continuously revised current GDP series, whose first quarter is 1994:Q1, is retroactive and alters the whole series at each release, there is a slight difference between GDP1, (at 447,159.1 trillion yen) and GDP2, (at 447,168.3 trillion yen) for $t = \text{first quarter of 1994}$. We link the two series at 1994:Q1 as
follows.

\[
GDP_t = \begin{cases} 
GDP_2 \times \lambda & \text{for } t = 1980:Q1 - 1993:Q4, \\
GDP_1 & \text{for } t = 1994:Q1 - 2014:Q1,
\end{cases}
\]  

where \( \lambda \) is the ratio of \( GDP_1 \) for \( t = 1994:Q1 \) to \( GDP_2 \) for \( t = 1994:Q1 \).

(ii) **METI’s Monthly All-Industry Activity Index.** This index is a Laspeyres index combining four subindexes: a construction industry index, the IP (the Index of Industrial Production), a services industry index, and a government services index. It therefore excludes agriculture. The latest base year is 2005, with a weight of 18.3% for the IP. METI has released two series, one whose base year is 2005 and the other (called the “link index”) that combines various past series with different base years, and the latter series is adjusted so that the two series can be concatenated to form a consistent series. The two seasonally adjusted series, along with a very brief documentation, can be downloaded from

(iii) **GDP Gap Estimate by the Cabinet Office.** In constructing potential quarterly GDP underlying their GDP gap estimate, the Cabinet Office uses a production function approach. A documentation (in Japanese) can be found in:

To summarize the document, the production function is Cobb-Douglas with 0.33 as capital’s share. Capital input is defined as an estimate of the capital stock (available from the National Income Accounts) times capacity utilization. Labor input is the number of persons employed times hours worked per person. The TFP (total factor productivity) level implied by this production function and actual quarterly, real, seasonally adjusted GDP is smoothed by the HP (Hodrick-Prescott) filter. Potential GDP is defined as the value implied by the production function with the smoothed TFP level. The capital and labor in this potential GDP calculation is also HP smoothed. The (quarterly) GDP gap is defined as: \( 100 \times \frac{\text{actual GDP} - \text{potential GDP}}{\text{potential GDP}} \).

The Cabinet Office does not release their potential GDP series, but they provide their current GDP gap series upon request. The GDP gap series we obtained is for 1980:Q1 - 2014:Q1. We verified, through email correspondences with them, that this series is to be paired with the quarterly GDP series released on June 9, 2014 (the GDP series described above). The GDP gap series is reproduced here (137 numbers):

0.3 -1.3 0.0 1.2 0.9 1.0 -0.2 -0.5 0.4 -0.2 -0.7 -0.4 -1.4 -1.4 -1.0 -1.2 -1.1 -0.5 -0.5 -1.4 -0.1 0.2 1.1

Construction of Potential Quarterly GDP. We can back out the Cabinet Office’s estimate of potential quarterly GDP by combining this series with the actual GDP series. For quarter \( t \), let \( GDP_t \) be (real, seasonally adjusted) GDP described in (i) above and let \( v_t \) be the GDP gap shown in (iii) above. The implied potential GDP for quarter \( t \), \( GDP_t^* \), satisfies the relation

\[
v_t = 100 \times \frac{GDP_t - GDP_t^*}{GDP_t^*}.
\]

Construction of Monthly Series. Given the two quarterly series, \( GDP_t \) (actual GDP) and \( GDP_t^* \) (potential GDP), we create the monthly output gap series \( x_t \) for January 1988-December 2012 as follows.
(i) Monthly Interpolation of GDP. Using the METI all-industry activity index described in (ii) above, the allocation of quarterly GDP between the three months constituting the quarter is done by the method of Chow and Lin (“Best Linear Unbiased Interpolation, Distribution, and Extrapolation of Time Series by Related Series”, Review of Economics and Statistics, Vol. 53, pp. 372-375, 1971). Quarterly GDP at annual rate for 1988:Q1-2012:Q4 is treated as the low frequency data, and the METI all-industry activity index for January 1988-December 2012 as the high frequency (monthly) indicator. The quarterly averages of interpolated series are constrained to be equal to the corresponding quarterly series. The estimation method is weighted least squares. Actual computation is done using Mr. Enrique M. Quilis’s Matlab code available from:

(ii) Monthly Interpolation of GDP∗. We used the spline method. A spline is fitted to GDP∗ for t = 1980:Q1 to 2012:Q4. The value of the interpolated monthly series for the middle month of the quarter is constrained to be equal to the quarterly series. We used the Matlab function “spline” for this operation.

(iii) Calculation of xt for January 1988-December 2012. Finally, using this smoothed monthly potential GDP and the monthly actual GDP, we define the monthly output gap for month t, xt, as

\[ xt \equiv 100 \times [\log(\text{actual GDP for month } t) - \log(\text{potential GDP for month } t)]. \]  

(A1.7)

HP-filtered GDP as Measure of Potential GDP In the other GDP gap series used in the paper, potential GDP is the HP-filtered actual GDP. To construct this GDP gap series, we first apply the HP (Hodrick-Prescott) filter to the log of actual quarterly GDP for 1980:Q1-2012:Q4. The smoothness parameter is the customary 1600. The exponent of this HP-filtered series is the potential quarterly GDP series. We then apply the same spline method to this series for 1980:Q1-2012:Q4, to obtain the monthly potential GDP series. Output gap for 1988:Q1-2012:Q4 is then calculated by the formula (A1.7).

Yield Spread
We construct the monthly long-term interest rate series using daily data on the zero coupon ten year yield (J01810Y) obtained from Bloomberg. The rate for month t is the average of daily values over the reserve maintenance period of the 16th of month t to the 15th of month t + 1. The yield spread is the difference between this monthly value and the policy rate for month t (\( r_t \)).

The Exchange Rate
We construct foreign exchange rate using daily data on the yen-dollar closing spot rate obtained from WM/Reuters. The rate for month t is the average of daily values over the reserve maintenance period of the 16th of month t to the 15th of month t + 1.

Bank Loans
We obtained monthly data on bank loans from the Bank of Japan. Specifically, we use “loans and bills discounted” in the banking account of domestically licensed banks (the Bank of Japan Website code: FA'FAABK_FAA2DBEA37). The value for the month is the average over the calendar month.

Stock Price Index
This index is used in the construction of Tobin’s q to be explained below. We construct the monthly stock price index using daily data on the closing value of Tokyo Stock Price Index (TOPIX) obtained from Bloomberg. The index for month t is the average of daily values over the reserve maintenance period of the 16th of month t to the 15th of month t + 1.
**Tobin’s q**

We follow three steps to construct monthly Tobin’s q ratio. The first step is a construction by interpolation of monthly series of the price investment goods. For the low frequency indicator, we use the quarterly series on the price of investment goods obtained from the National Income Accounts (NIA), compiled by the Cabinet office of the Japanese government. Specifically, we use the quarterly deflator for private non-resident investment gross capital formation classified by institutional sectors, downloadable from: http://www.esri.cao.go.jp/en/sna/data/kakuhou/files/2014/tables/26s16d_en.xls. We then fit the spline method (in the same manner as in our construction of the potential GDP interpolation above) to the quarterly series for $t = 1994Q1$ to $2012Q4$. In the second step, we divide the monthly stock price index by the interpolated monthly prices of investment goods (constructed in the first step), as input to the third step. In the third step, we conduct monthly interpolation of Tobin’s q using the method of Chow and Lin (in the same manner as described in the monthly GDP interpolation). For the high frequency indicator, we use the monthly variable constructed in the second step. For the low frequency series, we use the end-of-period annual series of Tobin’s q that can be calculated from the balance-sheet for non-financial corporations in the Japanese National Income Accounts, which is downloadable from http://www.esri.cao.go.jp/en/sna/data/kakuhou/files/2014/tables/26si12_en.xls.

Tobin’s q is defined as the ratio of the market value of liabilities (defined as the value of total liabilities less the value of financial assets) to the value of nonfinancial assets.

**U.S. Monthly Data on Inflation, Unemployment Rate, and the Policy Rate**

The price index used to compute inflation is the consumer price index for all urban consumers (all items, 1982-84=100) available from the BLS (Bureau of Labor Statistics). The BLS series id is CUSR0000SA0. This series is seasonally adjusted and available at monthly frequency. The unemployment rate is the civilian unemployment rate obtained from the BLS. The series id is LNS14000000. This series is seasonally adjusted and available at monthly frequency. It is expressed in percent. The policy rate is the effective federal funds rate from the Board of Governors of the Federal Reserve System. We take the average of daily values over the 16th day of the month to the 15th day of the following month. All 3 series are available from the FRED database website: http://www.research.stlouisfed.org/fred2/.
Appendix 2  Impulse Responses in Terms of Shocks

This section is a self-contained derivation of the shock-based translation of the three effects — the policy rate effect (6.5), the QE effect (6.7), and the transitional effect (the second component in (6.8)) — defined in Section 6 for our nonlinear model.

The Mapping and the Correspondence

The model, described in Section 4, is summarized by the mapping (4.8), reproduced here as

\[ (s_t, y_t) = f_t((\epsilon_t, v_t), I_{t-1}). \]  

Strictly for notational simplicity, the lagged information in (4.8), \((s_{t-1}, y_{t-1}, \ldots, y_{t-11})\), is written as \(I_{t-1}\), and the parameter vector has been suppressed. The variables of the system are \((s_t, y_t)\) (with \(y_t \equiv (p_t, x_t, r_t, m_t)\)) and the shock vector is \((\epsilon_t, v_t)\) where \(\epsilon_t\) is the bivariate reduced-form shock to inflation \((p_t)\) and output \((x_t)\) while \(v_t \equiv (v_{rt}, v_m, v_{sd})\) collects the monetary policy shocks, consisting of the Taylor rule shock \((v_{rt})\), the shock to the inflation threshold \((v_m)\), and the reserve supply shock \((v_{sd})\). The discrete variable of the model is \(s_t\) representing the monetary policy regime.

Conditional on lagged information \(I_{t-1}\), the mapping (4.8') is from the shock vector \((\epsilon_t, v_t)\) to the variables \((s_t, y_t)\). The inverse mapping is the correspondence \(\varphi\) from the variables to the shock vector defined by the set

\[ \varphi(s_t, y_t; I_{t-1}) \equiv \{ (\epsilon, v) \mid (s_t, y_t) = f_t((\epsilon, v), I_{t-1}) \}. \]  

As in the simple univariate example in the text, the correspondence is conditional on lagged information \(I_{t-1}\). Thus the set \(\varphi\) can — and will — depend on the lagged regime \(s_{t-1}\) which is part of \(I_{t-1}\).

The conditional expectations entering the definition of the three effects are conditional on the history of the variables. The translation of the effects is accomplished by rewriting those conditional expectations in terms of shocks. The rewriting can be done via \(\varphi\). For \(y = p, x, r, m\),

\[ E\{y_{t+k} \mid (\epsilon_t, v_t)\} \in \varphi(s_t, y_t; I_{t-1}, I_{t-1}) \]

\[ = E\{y_{t+k} \mid (s_t, y_t), I_{t-1}\} \quad \text{(by construction of } \varphi) \]

\[ = E\{y_{t+k} \mid (s_t, y_t), y_{t-1}, \ldots, y_{t-10}\}. \quad \text{(by the Markov property)} \]

The rest of this appendix is to describe this set \(\varphi\) for several relevant configurations of \((s_t, y_t)\).

Conditioning Expectations by Equalities and Inequalities on Shocks

The mapping (4.8') can be broken into two stages. In the first stage, the bivariate reduced form determines \((p_t, x_t)\) given \(I_{t-1}\) and \(\epsilon_t\). Let \((\hat{p}_t, \hat{x}_t)\) be the systematic component of \((p_t, x_t)\), so \((\hat{p}_t, \hat{x}_t)\) is a function of \(I_{t-1}\) and \((p_t, x_t)' = (\hat{p}_t, \hat{x}_t) + \epsilon_t\). The mapping from \(\epsilon_t\) to \((p_t, x_t)\) is one-to-one. In the second stage, given \((p_t, x_t, I_{t-1})\), the three monetary policy shocks \((v_{rt}, v_m, v_{sd})\) determine the regime \(s_t\), the policy rate \((r_t)\), and the excess reserve rate \((m_t)\). How \((s_t, r_t, m_t)\) is determined is described by (4.4)-(4.6) of the text. Since the mapping from \(\epsilon_t\) to \((p_t, x_t)\) in the first stage is one-to-one, the set \(\varphi\) can be written as

\[ \varphi(s_t, y_t; I_{t-1}) = \{ (\epsilon, v) \mid \epsilon = \left[ p_t - \frac{\hat{p}_t}{x_t - \hat{x}_t} \right], v \in \mathcal{V}(s_t, y_t, I_{t-1}) \}, \]  

where the set \(\mathcal{V}\) is determined by (4.4)-(4.6). The rewriting of the conditional expectations in the translation of the definition of the three effects then proceeds as follows. Recalling that
\[ I_{t-1} \equiv (s_{t-1}, y_{t-1}, \ldots, y_{t-11}). \]

\[
E\left( y_{t+k} \mid (s_t, y_t, y_{t-1}, \ldots, y_{t-10}) \right) = E\left( y_{t+k} \mid (s_t, y_t, I_{t-1}) \right) \quad \text{(by (A2.2))}
\]
\[
= \mathbb{E} \left[ y_{t+k} \mid \hat{e}_s \in \mathcal{V}(s_t, y_t, I_{t-1}) \right] \quad \text{(by (A2.3))}
\]

The question then boils down to charactering \( \mathcal{V} \) by (4.4)-(4.6). To reproduce (4.4)-(4.6) compactly here, we need to introduce additional notation. Let \( (r^s_t, m^s_{sd}) \) be the systematic components of \((r_t, m_{sd})\). So

\[
r^s_t \equiv \rho_t r^s_{t-1} + (1 - \rho_t)r_{t-1}, \quad m^s_{sd} \equiv \alpha_s + \beta_s' x_t \left[ \pi_t \right] + \gamma_s m_{t-1} \quad \text{(so \( m_{sd} = m^s_{sd} + v_{sd} \)).}
\]

(See (4.1) for the definition of \( r^s_t \), and (4.7) for \( m_{sd} \)). \( (r^s_t, m^s_{sd}) \) are functions of \((p_t, x_t, I_{t-1})\). Then (4.4)-(4.6) can be written as

\[
\begin{aligned}
\text{If } s_{t-1} = P, & \quad s_t = \begin{cases} P & \text{if } r^s_t + v_{rt} > \tilde{r}_t, \\ Z & \text{otherwise,} \end{cases} \\
\text{If } s_{t-1} = Z, & \quad s_t = \begin{cases} P & \text{if } r^s_t + v_{rt} > \tilde{r}_t \text{ and } \pi_t \geq \pi + v_{\pi}, \\ Z & \text{otherwise,} \end{cases}
\end{aligned}
\]

(\text{censored Taylor rule}) \quad r_t = \begin{cases} r^s_t + v_{rt} & \text{if } s_t = P, \\ \tilde{r}_t & \text{if } s_t = Z, \end{cases}

m_t = \begin{cases} 0 & \text{if } s_t = P, \\ \max\left[m^s_{sd} + v_{sd}, 0\right] & \text{if } s_t = Z. \end{cases}
\]

We now describe the set \( \mathcal{V}(s_t, y_t, I_{t-1}) \) for \( v \equiv (v_t, v_{\pi}, v_{\delta}) \) by equalities and inequalities on \( v \), for several configurations of \((s_t, y_t)\).

(a) \( s_t = P, y_t = (p_t, x_t, r_t, 0), r_t > \tilde{r}_t \). Thanks to the exit condition, the set depends on the previous regime \( s_{t-1} \in I_{t-1} \).

- Suppose first that \( s_{t-1} = P \). By (A2.6), we have \( s_t = P \) if and only if \( r^s_t + v_{rt} > \tilde{r}_t \) (i.e., iff the shadow Taylor rate is above the lower bound). Because the exit condition is mute, the threshold inflation \( \pi + v_{\pi} \) is irrelevant. Given \( s_t = P \), we have \( r_t = r^s_t + v_{rt} \) from (A2.7). For \( r_t > \tilde{r}_t \), the inequality condition “\( r^s_t + v_{rt} > \tilde{r}_t \)” is redundant. Because \( m_t = 0 \) regardless of \( v_{sd} \) under \( s_t = P \) by (A2.8), the money supply shock \( v_{sd} \) can be any value. Thus, if \( s_{t-1} = P \) and \( r_t > \tilde{r}_t \),

\[
\mathcal{V}(s_t = P, (p_t, x_t, r_t, 0), I_{t-1}) = \left\{ v \mid v_t = r_t - r^s_t, \ v_{\pi} \in \mathbb{R}, \ v_{\delta} \in \mathbb{R} \right\}.
\]
With this $V$, the rewriting of the conditional expectation (A2.4) for the current configuration of $(s_t, y_t)$ is:

$$
E\left(y_{t+k} \mid s_t = P_r(p_t, x_t, r_t), y_{t-1}, ..., y_{t-10}\right)
 = E\left(y_{t+k} \mid e_t = \frac{p_t - P}{x_t - \bar{x}_t}, v_{rt} = r_t - r_{t'}, s_{t-1} = P_r, y_{t-1}, ..., y_{t-11}\right).
$$  \hspace{1cm} (A2.10)

• Suppose next that $s_{t-1} = Z$. Now the exit condition kicks in and requires that the actual inflation exceed the threshold by (A2.6). Thus there should be an additional condition $\pi_t \geq \bar{\pi} + v_{\pi t}$. Thus, if $s_{t-1} = Z$ and $r_t > \bar{r}_t$,

$$
V(s_t = P_r(p_t, x_t, r_t), I_{t-1}) = \left\{ v \mid v_t = r_t - r_{t'}, v_{\pi t} \leq \pi_t - \bar{\pi}, v_s \in R \right\},
$$  \hspace{1cm} (A2.11)

so the same conditional expectation can be written as

$$
E\left(y_{t+k} \mid s_t = P_r(p_t, x_t, r_t), y_{t-1}, ..., y_{t-10}\right)
 = E\left(y_{t+k} \mid e_t = \frac{p_t - P}{x_t - \bar{x}_t}, v_{rt} = r_t - r_{t'}, v_{\pi t} \leq \pi_t - \bar{\pi}, s_{t-1} = Z, y_{t-1}, ..., y_{t-11}\right).
$$  \hspace{1cm} (A2.12)

(b) $s_t = Z$, $y_t = (p_t, x_t, \bar{r}_t, m_t)$, $m_t > 0$.

• Case: $s_{t-1} = P$. By (A2.6), we have $s_t = Z$ if and only if $r_{t'} \geq v_{rt} \leq \bar{r}_t$ (i.e., iff the shadow Taylor rate is below the lower bound). Because the exit condition is mute, the threshold inflation $\bar{\pi} + v_{\pi t}$ is irrelevant. Given $s_t = Z$, there is no further restriction on $v_{rt}$ because by (A2.7) $r_t = \bar{r}_t$ regardless of $v_{rt}$. By (A2.8), we have $m_t = \max[m_{t}' + v_{st}, 0]$. For $m_t > 0$, it must be that $m_{t}' + v_{st} = m_t$. Thus, if $s_{t-1} = P$ and $m_t > 0$,

$$
V(s_t = Z, (p_t, x_t, \bar{r}_t, m_t), I_{t-1}) = \left\{ v \mid v_t \leq \bar{r}_t - r_{t'}, v_{\pi t} \in R, v_s = m_t - m_{t}' \right\},
$$  \hspace{1cm} (A2.13)

so

$$
E\left(y_{t+k} \mid s_t = Z, (p_t, x_t, \bar{r}_t, m_t), y_{t-1}, ..., y_{t-10}\right)
 = E\left(y_{t+k} \mid e_t = \frac{p_t - P_t}{x_t - \bar{x}_t}, v_{rt} \leq \bar{r}_t - r_{t'}, v_{st} = m_t - m_{t}', s_{t-1} = P_r, y_{t-1}, ..., y_{t-11}\right).
$$  \hspace{1cm} (A2.14)

• Case: $s_{t-1} = Z$. The exit condition becomes relevant. The regime Z continues if either the shadow rate is below the lower bound or inflation is below the threshold. So $s_t = Z$ if and only if $r_{t'} + v_{rt} \leq \bar{r}_t$ or $\pi_t \leq \bar{\pi} + v_{\pi t}$. Thus, if $s_{t-1} = Z$ and $m_t > 0$,

$$
V(s_t = Z, (p_t, x_t, \bar{r}_t, m_t), I_{t-1}) = \left\{ v \mid (v_t \leq \bar{r}_t - r_{t'} \text{ or } v_{\pi t} \geq \pi_t - \bar{\pi}), v_s = m_t - m_{t}' \right\},
$$  \hspace{1cm} (A2.15)

55
so

\[ E\left(y_{t+k} \mid s_t = Z, (p_t, x_t, \bar{r}_t, m_t), y_{t-1}, ..., y_{t-10}\right) \]

\[ = E\left(y_{t+k} \mid E_t = \left[ \frac{p_t - p_t^0}{x_t - \bar{x}_t}, \ (v_{rs} \leq \bar{r}_t - r_t^0 \text{ or } v_{rt} > \pi_t - \bar{\pi}), \ v_{st} = m_t - m_{st}^e, \ s_{t-1} = Z, y_{t-1}, ..., y_{t-11}\right] \right)_{l_t} \]

(A2.16)

(c) \( s_t = Z, y_t = (p_t, x_t, \bar{r}_t, 0) \). Here, the only difference from the previous configuration is that \( m_t = 0 \). The restriction on \( v_{st} \) implied by the excess reserve supply equation \( m_t = \max[m^e_t + v_{st}, 0] \) is that \( m^e_t + v_{st} \leq 0 \). Thus,

- Case: \( s_{t-1} = P \).

\[ \mathcal{V}\left(s_t = Z, (p_t, x_t, \bar{r}_t, 0), I_{t-1}\right) = \left\{ v_t \mid v_t \leq \bar{r}_t - r_t^0, \ v_{\pi_t} \leq -m_{st}^e \right\}, \] (A2.17)

so

\[ E\left(y_{t+k} \mid s_t = Z, (p_t, x_t, \bar{r}_t, 0), y_{t-1}, ..., y_{t-10}\right) \]

\[ = E\left(y_{t+k} \mid E_t = \left[ \frac{p_t - p_t^0}{x_t - \bar{x}_t}, \ v_{rs} \leq \bar{r}_t - r_t^0, \ v_{st} \leq -m_{st}^e, \ s_{t-1} = P, y_{t-1}, ..., y_{t-11}\right] \right)_{l_t} \]  

(A2.18)

- Case: \( s_{t-1} = Z \).

\[ \mathcal{V}\left(s_t = Z, (p_t, x_t, \bar{r}_t, 0), I_{t-1}\right) = \left\{ v_t \mid v_t \leq \bar{r}_t - r_t^0 \text{ or } v_{\pi_t} > \pi_t - \bar{\pi}, \ v_{\pi_t} \leq -m_{st}^e \right\}, \] (A2.19)

so

\[ E\left(y_{t+k} \mid s_t = Z, (p_t, x_t, \bar{r}_t, 0), y_{t-1}, ..., y_{t-10}\right) \]

\[ = E\left(y_{t+k} \mid E_t = \left[ \frac{p_t - p_t^0}{x_t - \bar{x}_t}, \ (v_{rs} \leq \bar{r}_t - r_t^0 \text{ or } v_{\pi_t} > \pi_t - \bar{\pi}), \ v_{st} \leq -m_{st}^e, \ s_{t-1} = Z, y_{t-1}, ..., y_{t-11}\right] \right)_{l_t} \]  

(A2.20)

**Equivalent Statements in Terms of Shocks**

With the expectations conditioned on equalities and inequalities on the shocks, rather than on the variables, it is now straightforward to translate the responses in terms of shocks. As before, in the expressions below, “\( y \)” is either “\( p \)”, “\( x \)”, “\( r \)”, or “\( m \)”. 

56
The Policy-Rate Effect (6.5). By rewriting the two conditional expectations in (6.5) using (A2.10) and (A2.12), we obtain the translation: for \( r_t > \bar{r}_t \) and \( r_t + \delta_r > \bar{r}_t \),

\[
\begin{align*}
E(y_{t+k} \mid s_t = P, \quad (p_t, x_t, \bar{r}_t + \delta_r, 0), \quad y_{t-1}, ..., y_{t-10}) \\
\quad y_t = (p_t, x_t, r_t, m_t) \text{ in the alternative history} \\
- E(y_{t+k} \mid s_t = P, \quad (p_t, x_t, \bar{r}_t, 0), \quad y_{t-1}, ..., y_{t-10}) \\
\quad y_t = (p_t, x_t, r_t, m_t) \text{ in the baseline history}
\end{align*}
\]

\[
\begin{align*}
\begin{cases}
E(y_{t+k} \mid \varepsilon_t = \frac{p_t - \bar{p}_t}{x_t - \bar{x}_t}, \quad \nu_{rt} = r_t - r^*_t + \delta_r, \quad s_{t-1} = P, \quad y_{t-1}, ..., y_{t-11}) \\
- E(y_{t+k} \mid \varepsilon_t = \frac{p_t - \bar{p}_t}{x_t - \bar{x}_t}, \quad \nu_{rt} = r_t - r^*_t, \quad s_{t-1} = Z, \quad y_{t-1}, ..., y_{t-11}) \quad \text{if } s_{t-1} = P,
\end{cases}
\end{align*}
\]

\[
\begin{align*}
\begin{cases}
E(y_{t+k} \mid \varepsilon_t = \frac{p_t - \bar{p}_t}{x_t - \bar{x}_t}, \quad \nu_{rt} = r_t - r^*_t + \delta_r, \quad v_{rt} \leq \pi_t - \bar{\pi}_t, \quad s_{t-1} = Z, \quad y_{t-1}, ..., y_{t-11}) \\
- E(y_{t+k} \mid \varepsilon_t = \frac{p_t - \bar{p}_t}{x_t - \bar{x}_t}, \quad \nu_{rt} = r_t - r^*_t, \quad v_{rt} \leq \pi_t - \bar{\pi}_t, \quad s_{t-1} = Z, \quad y_{t-1}, ..., y_{t-11}) \quad \text{if } s_{t-1} = Z.
\end{cases}
\end{align*}
\]

Therefore, the only difference in the configuration of the shocks between the baseline and the alternative conditional expectations is that the interest rate shock \( \nu_{rt} \) differs by \( \delta_r \) in the alternative.

The QE Effect (6.7). Using (A2.14) and (A2.16), we obtain the translation: for \( m_t > 0 \) and \( m_t + \delta_m > 0 \),

\[
\begin{align*}
E(y_{t+k} \mid s_t = Z, \quad (p_t, x_t, \bar{r}_t, m_t + \delta_m), \quad y_{t-1}, ..., y_{t-10}) \\
\quad y_t = (p_t, x_t, r_t, m_t) \text{ in the alternative history} \\
- E(y_{t+k} \mid s_t = Z, \quad (p_t, x_t, \bar{r}_t, m_t), \quad y_{t-1}, ..., y_{t-10}) \\
\quad y_t = (p_t, x_t, r_t, m_t) \text{ in the baseline history}
\end{align*}
\]

\[
\begin{align*}
\begin{cases}
E(y_{t+k} \mid \varepsilon_t = \frac{p_t - \bar{p}_t}{x_t - \bar{x}_t}, \quad \nu_{rt} \leq \bar{\pi}_t - r^*_t, \quad v_{rt} = m_t - m^*_t + \delta_m, \quad s_{t-1} = P, \quad y_{t-1}, ..., y_{t-11}) \\
- E(y_{t+k} \mid \varepsilon_t = \frac{p_t - \bar{p}_t}{x_t - \bar{x}_t}, \quad \nu_{rt} \leq \bar{\pi}_t - r^*_t, \quad v_{rt} = m_t - m^*_t, \quad s_{t-1} = P, \quad y_{t-1}, ..., y_{t-11}) \quad \text{if } s_{t-1} = P,
\end{cases}
\end{align*}
\]

\[
\begin{align*}
\begin{cases}
E(y_{t+k} \mid \varepsilon_t = \frac{p_t - \bar{p}_t}{x_t - \bar{x}_t}, \quad \nu_{rt} \leq \bar{\pi}_t - r^*_t, \quad v_{rt} > \pi_t - \bar{\pi}_t, \quad v_{rt} = m_t - m^*_t + \delta_m, \quad s_{t-1} = Z, \quad y_{t-1}, ..., y_{t-11}) \\
- E(y_{t+k} \mid \varepsilon_t = \frac{p_t - \bar{p}_t}{x_t - \bar{x}_t}, \quad \nu_{rt} \leq \bar{\pi}_t - r^*_t, \quad v_{rt} > \pi_t - \bar{\pi}_t, \quad v_{rt} = m_t - m^*_t, \quad s_{t-1} = Z, \quad y_{t-1}, ..., y_{t-11}) \quad \text{if } s_{t-1} = Z.
\end{cases}
\end{align*}
\]

(A2.21)
Again, the only difference in the configuration of the shocks is that the excess reserve shock \( v_{st} \) differs by \( \delta m \) in the alternative.

**The Transitional Effect (the second component in (6.8)).** Using (A2.10) and (A2.18), and (A2.12) and (A2.20), we obtain the translation:

\[
E \left( y_{t+k} \mid s_t = Z, \ (p_t, x_t, \tilde{r}_t, 0) \right) \ y_{t-1}, \ldots, y_{t-10} \\
- \lim_{r_{t} \downarrow} E \left( y_{t+k} \mid s_t = P, \ (p_t, x_t, \tilde{r}_t, 0) ; \ y_{t-1}, \ldots, y_{t-10} \right)
\]

\[
y_t \equiv (p_t, x_t, r_t, m_t) \text{ in the alternative history}
\]

\[
y_t \equiv (p_t, x_t, r_t, m_t) \text{ in the baseline history}
\]

\[
\begin{dcases}
E \left( y_{t+k} \mid \xi_t = \left[ \frac{p_t - \hat{p}_t}{\tilde{x}_t - \bar{x}_t} \right] \right) \left. \right| \ s_t = P, \ (p_t, x_t, \tilde{r}_t, 0) ; \ y_{t-1}, \ldots, y_{t-11} \\
- \lim_{r_{t} \downarrow} E \left( y_{t+k} \mid \xi_t = \left[ \frac{p_t - \hat{p}_t}{\tilde{x}_t - \bar{x}_t} \right] \right) \left. \right| \ s_t = P, \ (p_t, x_t, \tilde{r}_t, 0) ; \ y_{t-1}, \ldots, y_{t-11} \text{ if } s_{t-1} = P
\end{dcases}
\]

\[
\begin{dcases}
E \left( y_{t+k} \mid \xi_t = \left[ \frac{p_t - \hat{p}_t}{\tilde{x}_t - \bar{x}_t} \right] \right) \left. \right| \ s_t = Z, \ (p_t, x_t, \tilde{r}_t, 0) ; \ y_{t-1}, \ldots, y_{t-11} \\
- \lim_{r_{t} \downarrow} E \left( y_{t+k} \mid \xi_t = \left[ \frac{p_t - \hat{p}_t}{\tilde{x}_t - \bar{x}_t} \right] \right) \left. \right| \ s_t = Z, \ (p_t, x_t, \tilde{r}_t, 0) ; \ y_{t-1}, \ldots, y_{t-11} \text{ if } s_{t-1} = Z
\end{dcases}
\]

(A2.23)
Appendix 3  The Analytical Expression for the Transitional Effect

We focus on the the immediate response for \((p, x)\), namely their IR at \(k = 1\) (one period ahead), because it can be calculated analytically. Write the reduced form for period \(t + 1\) as:

\[
\begin{bmatrix}
  p_{t+1} \\
  x_{t+1}
\end{bmatrix} = \begin{bmatrix}
  c(s_t) + \phi_g(s_t)g_{t+1} \\
  \phi_p(p_t)p_t + \phi_x(s_t)x_t + \phi_r(s_t)r_t + \phi_m(s_t)m_t + \varepsilon_{t+1}
\end{bmatrix} = \begin{bmatrix}
  \Phi(p_{t+1}) \\
  \Phi(x_{t+1})
\end{bmatrix}
\]

where \(g_{t+1}\) is the concurrent trend growth rate (the 12-month growth rate of potential output to month \(t + 1\)). We can interpret the term in braces, \(c(s_t) + \phi_g(s_t)g_{t+1}\), as the time-varying intercept. Our estimates of the coefficients can be read off from Table 6. For example,

\[
c(P) = \begin{bmatrix}
  0.12 \\
  -0.88
\end{bmatrix}, \quad \Phi = \begin{bmatrix}
  -0.57 \\
  -0.99 \\
  -0.51 \\
  1.31
\end{bmatrix}, \quad \Phi_g(Z) = \begin{bmatrix}
  -0.24 \\
  0.03
\end{bmatrix}.
\]

The immediate response to the regime change from P to Z comes from the change in the reduced-form coefficients. Since \(r_t = \bar{r} = 0\) and \(m_t = 0\) in the PZ-IR, we have:

\[
\begin{bmatrix}
  \text{PZ-IR of } p \text{ at } k = 1 \\
  \text{PZ-IR of } x \text{ at } k = 1
\end{bmatrix} = \begin{bmatrix}
  \{c(Z) - c(P)\} + [\Phi_g(Z) - \Phi_g(P)]g_{t+1} \\
  [\Phi_x(Z) - \Phi_x(P)]x_t + [\Phi_r(Z) - \Phi_r(P)]r_t + [\Phi_m(Z) - \Phi_m(P)]m_t + \varepsilon_{t+1}
\end{bmatrix}
\]

For the base period of \(t = \text{July 2006}\), we have \(p_t = -0.3\), \(x_t = -0.8\) from Table 2. Also, \(\bar{r} = 0\) and \(g_{t+1} = 0.86\). Thus, for \(t = \text{July 2006}\),

\[
\begin{bmatrix}
  \text{PZ-IR of } p \text{ at } k = 1 \\
  \text{PZ-IR of } x \text{ at } k = 1
\end{bmatrix} = \begin{bmatrix}
  \{0.57 - 0.12\} + \{0.24 - (-0.51)\} \times 0.86 \\
  -0.06 - (-0.09) \times -0.3 + 0.12 - 0.13 \times (-0.8)
\end{bmatrix} = \begin{bmatrix}
  -0.46 \\
  1.1
\end{bmatrix}.
\]

This shows that the primary source of the immediate response of \((-0.46, -1.1)\) is the difference between the regimes in the time-varying intercept. More specifically for \(p\), the difference is due to the constant term \(c(s_t)\); for \(x\), it is due to the difference in the trend growth coefficient in the reduced form.

---

36 There is no need to include the Mieno (anti-bubble) and banking crisis dummies in the reduced form because their values are zero for the base period in question.
Appendix 4  The Model and Derivation of the Likelihood Function

This appendix has two parts. The first is a self-contained exposition of the model with two regimes (P and Z) and with the excess reserve demand. The second part derives the likelihood function for the model.

The Model

The state vector of the model consists of a vector of continuous state variables \( y_t \) and a discrete state variable \( s_t \) (= P, Z). The continuous state \( y_t \) has the following elements:

\[
y_t \equiv \begin{bmatrix} y_{1t} \\ r_t \\ m_t \end{bmatrix}, \quad y_{1t} \equiv \begin{bmatrix} p_t \\ x_t \end{bmatrix},
\]

where \( p = \) monthly inflation rate, \( x = \) output gap, \( r = \) policy rate, and \( m = \) excess reserve rate. The model also involves a vector of exogenous variables, \( x_t \). It includes \( \bar{r}_t \), the rate paid on reserves. It can include other variables (such as the banking crisis dummy), but the identity of those other exogenous variables is immaterial in the derivation of the likelihood function below.

The model is a mapping from

\[
(s_{t-1}, y_{t-1}, ..., y_{t-11}, x_t, \epsilon_t, v_{rt}, v_{\pi t}, v_{\mu t}, v_{dt})
\]

to \((s_t, y_t)\). Here, \((\epsilon_t, v_{rt}, v_{\pi t}, v_{\mu t}, v_{dt})\) are mutually and serially independent shocks. We need to include 11 lags of \( y \) because of the appearance of the 12-month inflation rate in the model, see (A4.3) below. The mapping is defined as follows.

(i) (\( y_{1t} \) determined) \( \epsilon_t \) is drawn from \( \mathcal{N}(0, \Omega(s_{t-1})) \) and \( y_{1t} \) (the first two elements of \( y_t \)) is given by

\[
y_{1t} = c(s_{t-1}) + A(s_{t-1})x_t + \Phi(s_{t-1})y_{t-1} + \epsilon_t.
\]

Here, only one lag is allowed, strictly for expositional purposes; more lags can be included without any technical difficulties. The matrix \( A(s_{t-1}) \) has two rows. The number of its columns equals the dimension of the vector of exogenous variables \( x_t \).

(ii) (\( s_t \) determined) Given \( y_{1t} \) and \((y_{t-1}, ..., y_{t-11})\), the central bank calculates (through \((p_{t-1}, ..., p_{t-11}, x_t, r_{t-1})\))

\[
\pi_t \equiv \frac{1}{12} (p_t + \cdots + p_{t-1}) , \quad r'_t \equiv \alpha_r x_t + \beta_r \begin{bmatrix} \pi_t \\ x_t \end{bmatrix} + \gamma_r r_{t-1}.
\]

The central bank draws \((v_{rt}, v_{\pi t})\) from \( \mathcal{N}(0, \Omega) \), and determines \( s_t \) as

\[
\text{If } s_{t-1} = P, \quad s_t = \begin{cases} P & \text{if } r'_t + v_{rt} > \bar{r}_t, \\ Z & \text{otherwise}. \end{cases}
\]

\[
\text{If } s_{t-1} = Z, \quad s_t = \begin{cases} P & \text{if } r'_t + v_{rt} > \bar{r}_t \text{ and } \pi_t \geq \bar{\pi} + v_{\pi t}, \\ Z & \text{otherwise}. \end{cases}
\]
The likelihood of the data is (with its dependence on the parameter vector left implicit)

\[
\begin{align*}
\text{Derivation of the Likelihood Function} \\
\text{Note that } r_t \text{ in } (A4.5a) \text{ is guaranteed to be } > r_\text{t} \text{ under } \mathbb{P} \text{ because by } (A4.4a) \text{ and } (A4.4b) r_t^* + \nu_t > r_t \\
\text{if } s_t = \mathbb{P}.
\end{align*}
\]

(iv) \( (m_t \text{ determined}) \) Finally, the central bank draws \( v_{dl} \) from \( \mathcal{N}(0, \sigma_d^2) \) and the market draws \( v_{dl} \) from \( \mathcal{N}(0, \sigma_d^2) \). The excess reserve rate \( m_t \) is determined as

\[
\begin{align*}
\text{if } s_t = \mathbb{P}, \text{ then } m_t = \max \left[ m_{dl}^r + v_{dl}, 0 \right], \quad v_{dl} \sim \mathcal{N}(0, \sigma_d^2), & \quad (A4.6a) \\
\text{if } s_t = \mathbb{Z}, \text{ then } m_t = \max \left[ m_{dl}^r + v_{dl}, 0 \right], \quad v_{dl} \sim \mathcal{N}(0, \sigma_d^2), & \quad (A4.6b)
\end{align*}
\]

where,

\[
\begin{align*}
m_{dl}^r & \equiv \alpha_d + \beta_d^r \pi_t + \beta_d^r x_t + \beta_d x_t r_t, \\
m_{dl} & \equiv \alpha_s + \beta_s \pi_t + \beta_s x_t + \gamma_s m_{dl,t-1}.
\end{align*}
\]

When \( s_t = \mathbb{P} \) and \( s_{t-1} = \mathbb{Z} \), we set \( m_{dl,t-1} = 0 \); otherwise both \( m_{s,t-1} \) and \( m_{dl,t-1} \) are equal to \( m_{t-1} \).

Thus, formally, \( m_{s,t-1} \) and \( m_{dl,t-1} \) are functions of \( (s_t, s_{t-1}, m_{t-1}) \).

Let \( \theta \) be the model’s parameter vector. It consists of four groups:

\[
\begin{align*}
\theta_A &= (c(s), A(s), \phi(s), \omega(s), s = \mathbb{P}, \mathbb{Z}), \\
\theta_B &= (\alpha_r, \alpha_d, \beta_s, \gamma_s, \sigma_r, \pi_t, \sigma_d), \\
\theta_C &= (\alpha_s, \beta_s, \gamma_s, \sigma_s), \\
\theta_D &= (\alpha_d, \beta_d, \gamma_d, \sigma_d).
\end{align*}
\]

Derivation of the Likelihood Function

The likelihood of the data is (with its dependence on the parameter vector left implicit)

\[
\mathcal{L} \equiv p(s_1, ..., s_T, y_1, ..., y_T | x, Z_0),
\]

Here, \( x \equiv (x_T, x_{T-1}, ..., x_1) \), \( Z_t \equiv (s_t, s_{t-1}, ..., y_t, y_{t-1}, ..., y_1) \), and \( p(\cdot) \) is the joint density-distribution function of \( (s_1, ..., s_T, y_1, ..., y_T) \) conditional on \( (x, Z_0) \). The usual sequential factorization yields

\[
\mathcal{L} = \prod_{t=1}^{T} p(s_t, y_t | x, Z_{t-1}).
\]

Consider the likelihood for date \( t, p(s_t, y_t | x, Z_{t-1}) \) in (A4.10). Since \( x_0 \) is exogenous, it can be written as

\[
p(s_t, y_t | x, Z_{t-1}) = p(s_t, y_t | x_s, x_{t-1}, ..., Z_{t-1}).
\]

Recalling that \( y_t = (y_{1t}, r_t, m_t) \), we rewrite this date \( t \) likelihood as

\[
p(s_t, y_t | x_s, x_{t-1}, ..., Z_{t-1}) = p(m_t | r_t, s_t, y_{1t}, x_t, x_{t-1}, ..., Z_{t-1})
\times p(r_t | s_t, y_{1t}, x_t, x_{t-1}, ..., Z_{t-1})
\times \text{Prob}(s_t | y_{1t}, x_t, x_{t-1}, ..., Z_{t-1})
\times p(y_{1t} | x_s, x_{t-1}, ..., Z_{t-1}).
\]

In what follows, we rewrite each of the four terms on the right hand side of this equation in terms of the model parameters.
The Fourth Term, \( p(y_{1t} | x_t, x_{t-1}, ..., Z_{t-1}) \)

This term is entirely standard:

\[
p(y_{1t} | x_t, x_{t-1}, ..., Z_{t-1}) = b\left(y_{1t} - \left(c(s_{t-1}) + A(s_{t-1})x_t + \Phi(s_{t-1})y_{1t-1}\right); \Omega(s_{t-1})\right),
\]

(A4.13)

where \( b(\cdot; \Omega) \) is the density of the bivariate normal with mean \( \mathbf{0} \) and variance-covariance matrix \( \Omega \n (2\times2) \).

\[
\text{The Third Term, } \text{Prob}(s_t | y_{1t}, x_t, x_{t-1}, ..., Z_{t-1}) \]

This is the transition probability matrix for \( \{s_t\} \). The probabilities depend on \((r_t, \pi_t, r)\) (which in turn can be calculated from \((y_{1t}, x_t, Z_{t-1})\), see (A4.3)). They are easy to derive from (A4.4a) and (A4.4b):

\[
\begin{array}{ccc}
\text{s}_{t-1} & \text{P} & \text{Z} \\
\hline
\text{P} & P_{rt} & 1 - P_{rt} \\
\text{Z} & P_{rt}P_{rt} & 1 - P_{rt}P_{m_t}
\end{array}
\]

Here,

\[
P_{rt} \equiv \text{Prob} \left( r_t^r + v_r > \bar{r}_t | r_t, \bar{r}_t \right) = \Phi \left( \frac{r_t - \bar{r}_t}{\sigma_r} \right),
\]

(A4.14)

\[
P_{mt} \equiv \text{Prob} \left( \pi_t \geq \pi + v_{\pi_t} | \pi_t \right) = \Phi \left( \frac{\pi_t - \pi}{\sigma_{\pi}} \right),
\]

(A4.15)

where \( \Phi(.) \) is the cdf of \( N(0,1) \).

The First Term, \( p(m_t | r_t, s_t, y_{1t}, x_t, x_{t-1}, ..., Z_{t-1}) \)

\( m_t \) is given by (A4.6a) and (A4.6b). The right-hand-side variables in those equations, including \( m_{d,t-1} \) and \( m_{s,t-1} \), are functions of \((r_t, s_t, y_{1t}, x_t, Z_{t-1})\). So this term is the Tobit distribution-density function given by

\[
h_{jt} \equiv \frac{1}{\sigma_j} \phi \left( \frac{m_{jt} - m_{jt}^c}{\sigma_j} \right)^{1(m_{jt} > 0)} \times \left[ 1 - \Phi \left( \frac{m_{jt}^c}{\sigma_j} \right) \right]^{1(m_{jt} = 0)},
\]

(A4.16)

where \( 1(.) \) is the indicator function, \( \phi(.) \) and \( \Phi(.) \) are the density and the cdf of \( N(0,1) \).

The Second Term, \( p(r_t | s_t, y_{1t}, x_t, x_{t-1}, ..., Z_{t-1}) \)

If \( s_t = Z \), then \( r_t = \bar{r}_t \) with probability 1, so this term can be set to 1. If \( s_t = P \), there are two cases to consider.
• For \(s_{t-1} = P\),

\[
p(r_t | s_t = P, y_{1t}, x_t, x_{t-1}, ..., Z_{t-1}) = p\left(r_t^p + v_{rt} | r_t^p + v_{rt} > \bar{r}_t, r_t^p, \bar{r}_t \right)
\]

(by (A4.4a) and (A4.5a) and since \((r_t^p, \bar{r}_t)\) is a function of \((y_{1t}, x_t, Z_{t-1})\))

\[
= \frac{p\left(r_t^p + v_{rt} | r_t^p\right)}{\text{Prob}\left(r_t^p + v_{rt} > \bar{r}_t | r_t^p, \bar{r}_t\right)}
\]

\[
= \frac{\frac{1}{\sqrt{2\pi}\sigma_r} \phi\left(\frac{r_t^p}{\sigma_r}\right)}{\text{Prob}\left(r_t^p + v_{rt} > \bar{r}_t | r_t^p, \bar{r}_t\right)}
\]

(b/c \(r_t^p + v_{rt} \sim \mathcal{N}(r_t^p, \sigma_r^2)\))

\[
= \frac{\frac{1}{\sigma_r} \phi\left(\frac{r_t^p - \bar{r}_t}{\sigma_r}\right)}{P_{rt}}
\]

(b/c \(P_{rt} = \text{Prob}(r_t^p + v_{rt} > \bar{r}_t | r_t^p)\))  \hspace{1cm} (A4.17)

• For \(s_{t-1} = Z\),

\[
p(r_t | s_t = Z, y_{1t}, x_t, x_{t-1}, ..., Z_{t-1}) = p\left(r_t^p + v_{rt} | r_t^p + v_{rt} > \bar{r}_t, \pi_t \geq \bar{\pi} + v_{rt}, r_t^p, \bar{r}_t, \pi_t \right)
\]

(by (A4.4b) and (A4.5a) and since \((r_t^p, \bar{r}_t, \pi_t)\) is a function of \((y_{1t}, x_t, Z_{t-1})\))

\[
= p\left(r_t^p + v_{rt} | r_t^p + v_{rt} > \bar{r}_t, r_t^p, \bar{r}_t \right)
\]

(b/c \(v_{rt}\) and \(v_{rt}\) are independent)

\[
= \frac{1}{\sigma_r} \phi\left(\frac{r_t^p - \bar{r}_t}{\sigma_r}\right)
\]

(as above).  \hspace{1cm} (A4.18)

**Putting All Pieces Together**

Putting all those pieces together, the likelihood for date \(t\), (A4.12), can be written as (with \(X_t\) here denoting \((x_t, x_{t-1}, ..., )\) for brevity)

| \(s_{t-1}\) | \(p(m_t | r_t, s_t, y_{1t}, X_t, Z_{t-1})\) | \(p(r_t | s_t, y_{1t}, X_t, Z_{t-1})\) | \(\text{Prob}(s_t | y_{1t}, X_t, Z_{t-1})\) | \(f(y_{1t} | X_t, Z_{t-1})\) |
|---|---|---|---|---|
| \(P\) | \(h_{dlt}\) | \(\frac{g_t}{P_{rt}}\) | \(P_{rt}\) | \(f_{dlt}\) |
| \(P\) | \(h_{dt}\) | \(\frac{g_t}{P_{rt}}\) | \(P_{rt}P_{nl}\) | \(f_{dl}\) |
| \(Z\) | \(h_{dlt}\) | \(1\) | \(1 - P_{rt}\) | \(f_{dt}\) |
| \(Z\) | \(h_{dl}\) | \(1\) | \(1 - P_{rt}P_{nl}\) | \(f_{dz}\) |

Here,

\[
f_{dlt} \equiv b\left(y_{1t} - c(P) - a(P)d_t - \Phi(P)y_{1t-1}; \Omega(P)\right),
\]

\[
f_{dl} \equiv b\left(y_{1t} - c(Z) - a(Z)d_t - \Phi(Z)y_{1t-1}; \Omega(Z)\right),
\]

\[
g_t \equiv \frac{1}{\sigma_r} \phi\left(\frac{r_t^p - \bar{r}_t}{\sigma_r}\right),
\]

\[
P_{rt} \equiv \Phi\left(\frac{r_t^p - \bar{r}_t}{\sigma_r}\right),
\]

\[
P_{nl} \equiv \Phi\left(\frac{\pi_t - \bar{\pi}}{\sigma_{\pi}}\right),
\]

\(h_{dlt}\) is defined in (A4.16) and \(b(\cdot; \Omega)\) is the density function of the bivariate normal distribution with mean \(0\) and variance-covariance matrix \(\Omega\).  \((2 \times 2)\)
Dividing it into Pieces

Taking the log of both sides of (A4.10) while taking into account (A4.11) and (A4.12) and substituting the entries in the table, we obtain the log likelihood of the sample:

\[ L \equiv \log(L) = \sum_{i=1}^{T} \log[p(s_i, y_i | x_i, x_{i-1}, ..., Z_{i-1})] = L_A + L_1 + L_2 + L_D, \]

where

\[ L_A = \sum_{s_{t-1}=P} \log[f_{Pt}] + \sum_{s_{t-1}=Z} \log[f_{Zt}], \quad (A4.19) \]

\[ L_1 = \sum_{s_t=P} \log[P_{rt}] + \sum_{s_{t-1}=P|Z} \log[P_{rt}] + \sum_{s_{t-1}=Z|P} \log[1 - P_{rt}] + \sum_{s_{t-1}=Z|Z} \log[1 - P_{rt}P_{nt}], \quad (A4.20) \]

\[ L_2 = \sum_{s_t=P} [\log(g_t) - \log(P_{rt})] + \sum_{s_{t-1}=Z} \log[h_{st}], \quad (A4.21) \]

\[ L_D = \sum_{s_t=Z} \log[h_{st}], \quad (A4.22) \]

The terms in \( L_1 + L_2 \) can be regrouped into \( L_B \) and \( L_C \), as in

\[ L = L_A + \underbrace{L_B + L_C + L_D}_{=L_1 + L_2}, \quad (A4.23) \]

where

\[ L_B = \sum_{s_t=P} \log[g_t] + \sum_{s_{t-1}=P|Z} \log[P_{rt}] + \sum_{s_{t-1}=Z|P} \log[1 - P_{rt}] + \sum_{s_{t-1}=Z|Z} \log[1 - P_{rt}P_{nt}], \quad (A4.24) \]

\[ L_C = \sum_{s_t=Z} \log[h_{st}], \quad (A4.25) \]

\( L_A, L_B, L_C \) and \( L_D \) can be maximized separately, because \( L_j \) depends only on \( \theta_j \) \( (j = A, B, C, D) \) \((\theta_A, \theta_B, \theta_C, \theta_D) \) was defined in (A4.8) above).

As a special case, consider simplifying step (ii) of the mapping above by replacing (A4.4a) and (A4.4b) by

\[ s_t = \begin{cases} 
P & \text{if } r_t' + v_{rt} > \bar{r}_t, \\
Z & \text{otherwise}. 
\end{cases} \quad (A4.26) \]

Namely, drop the exit condition. This is equivalent to constraining \( P_{nt} \) to be 1, so \( L_B \) becomes

\[ L_B = \sum_{s_t=P} \log[g_t] + \sum_{s_{t-1}=Z} \log[1 - P_{rt}], \quad (A4.27) \]

which is the Tobit log likelihood function.

64
Appendix 5: A Simple Example of Expansionary Exits

This Appendix provides an example in which policy-induced exits from the zero-rate regime are expansionary. It is a variant of the well-known two-equation new Keynesian model of Eggertson and Woodford (2003) of the severity of the zero lower bound. As in their analysis, we seek an equilibrium in which the endogenous variables are time-invariant functions of the state of the world governed by a two-state Markov chain with one absorbing state. The exogenous variable in their model is the real interest rate, while in ours it is the monetary policy shock. Solely to provide a simplest possible example, we replace their two-equations by the Fisher equation, thus dropping the output gap from the model. As in most theoretical analysis of the zero lower bound but contrary to the recursive model of the text, the inflation rate and the nominal interest rate are determined simultaneously.

Let $\omega_t$ be the state of the world whose value is either 0 or 1. Represent the mapping from the state to the endogenous variables $(\pi_t, r_t)$ (where $\pi_t$ is the inflation rate and $r_t$ is the nominal interest rate) as

$$(\pi_t, r_t) = (\pi(\omega_t), r(\omega_t)), \quad \pi(0) \equiv \pi(0), \quad \pi(1) \equiv \pi(1), \quad r(0) \equiv r(0), \quad r(1) \equiv r(1).$$

(A5.1)

State 1 is the absorbing state. Since we are interested in exits, the path of the state we consider is such that the initial state is state 0. As time progresses, the state $\omega_t$ switches from state 0 to 1. In each period, the probability of the switch is $q$ with $0 < q < 1$. If the current state is $\omega_t = 1$ in period $t$, then $(\pi_t, r_t)$ will be constant from $t$ on, so the Fisher equation is

$$r(1) = \rho + \pi(1),$$

(A5.2)

where $\rho$ is the constant real interest rate. We assume throughout that $\rho > 0$. If the current state is $\omega_t = 0$, then the next period’s inflation rate $\pi_{t+1}$ is $\pi(0)$ with probability $q$ and $\pi(1)$ with probability $1 - q$, so the Fisher equation is

$$r(0) = \rho + q\pi(0) + (1 - q)\pi(1).$$

(A5.3)

We show below that the following equilibrium

$$(\pi(0), r(0)) = \left(-\frac{\rho}{q}, 0\right), \quad (\pi(1), r(1)) = (0, \rho)$$

(A5.4)

is supported by the Taylor rule.

To describe the Taylor rule, define the shadow rate $\tilde{r}_t$ as

$$\tilde{r}_t \equiv \rho + \phi \pi_t + v_t.$$  

(A5.5)

Here, $v_t$ is the monetary policy shock taken to be exogenous to the model. We assume the Taylor principle, so $\phi > 1$. The mapping from the state to the monetary policy shock is assumed to be

$$v_t = \begin{cases} v & \text{if } \omega_t = 0, \\ 0 & \text{if } \omega_t = 1. \end{cases}$$

(A5.6)

We assume $v > 0$. Let $s_t$, which is either P or Z, be the monetary policy regime. It will turn out that the regime and the state agree completely (i.e., $s_t = P$ whenever $\omega_t = 1$ and $s_t = Z$ whenever $\omega_t = 0$). The censored Taylor rule with an inflation exit condition attached to it is described by

$$(\text{censored Taylor rule}) \quad r_t = \begin{cases} \tilde{r}_t & \text{if } s_t = P, \\ 0 & \text{if } s_t = Z. \end{cases}$$

(A5.7)
with the evolution of the regime governed by

\[
\begin{align*}
\text{If } s_{t-1} = P, \quad & s_t = \begin{cases} 
P & \text{if } \tilde{\tau}_t > 0, \\
Z & \text{otherwise.}
\end{cases} \\
\text{If } s_{t-1} = Z, \quad & s_t = \begin{cases} 
P & \text{if } \tilde{\tau}_t > 0 \text{ and } \pi_t \geq \pi_t, \\
Z & \text{otherwise,}
\end{cases}
\end{align*}
\]

(A5.8)

where \(\pi_t\) is the threshold inflation rate. The Taylor rule considered in the text reduces to this if (i) there is no lags in adjusting the policy rate (so the shadow Taylor rate and the desired rate coincide) and (ii) the rate \(r_t\) paid on reserves is 0. Throughout this first example, the threshold inflation rate \(\pi_t\) is constant at zero.

We now exhibit a policy-induced exit that is inflationary.

(a) The state of the world \(\omega_t\) is either 0 or 1. Suppose \(\omega_t = 1\), so \(v_t = 0\) in (A5.5). The inflation rate and the nominal rate under this state, \((\pi^{(1)}(1), r^{(1)}(1))\), have to satisfy the Fisher equation (A5.2) and the Taylor rule.

(i) If the previous regime \(s_{t-1} = P\), then, by (A5.5)-(A5.8), the Taylor rule becomes

\[
r^{(1)} = \begin{cases} 
\rho + \phi \pi^{(1)} & \text{if } \rho + \phi \pi^{(1)} > 0, \\
0 & \text{otherwise.}
\end{cases}
\]

(A5.9)

As noted by Benhabib, Schmitt-Grohe, and Uribe (2001), there are two solutions for \((\pi^{(1)}(1), r^{(1)}(1))\) to the Fisher equation and the Taylor rule. Those two equilibria are indicated in Appendix Figure 4a as points A and B. In the figure, the graph of the Fisher equation is the 45 degree line passing through \((0, \rho)\). The graph of the Taylor rule is the kinked dotted line due to the zero lower bound. The kink occurs where the straight line with a slope of \(\phi > 0\) hits the horizontal axis. Those two graphs have two intersections, points A and B. Point B is often called the liquidity trap. Following the mainstream literature, we assume that the “good” equilibrium, point A, is chosen. At point A, the shadow rate \(\tilde{\tau}_t = \rho + \phi \pi_t\) is positive, so the regime \(s_t = P\).

(ii) If the previous regime is \(s_{t-1} = Z\), then the exit condition kicks in and the Taylor rule (with the threshold inflation rate \(\pi_t\) set to 0) is

\[
r^{(1)} = \begin{cases} 
\rho + \phi \pi^{(1)} & \text{if } \rho + \phi \pi^{(1)} > 0 \text{ and } \pi^{(1)} \geq 0, \\
0 & \text{otherwise.}
\end{cases}
\]

(A5.10)

Appendix Figure 4b shows the Fisher equation and the Taylor rule. The graph of the Fisher equation is the same as in the previous figure, but the Taylor rule now has a discontinuity occurring at \(\pi^{(1)} = 0\). Still, the two graphs have the same two intersections, points A and B. We assume that the good equilibrium A is chosen.

We have thus shown that \((s_t, \pi_t, \tau_t) = (P, 0, \rho)\) if \(\omega_t = 1\).

(b) Suppose \(\omega_t = 0\), so \(v_t = v > 0\). We show that \((s_t, \pi_t, \tau_t) = (Z, -\rho/q, 0)\) provided \(s_{t-1} = Z\). Since \(\pi^{(1)} = 0\) as just shown, the Fisher equation (A5.3) that the inflation rate and the nominal rate under state 0, \((\pi^{(0)}, r^{(0)})\), have to satisfy is

\[
r^{(0)} = \rho + q \pi^{(0)}.
\]

(A5.11)
Since the previous regime is $Z$, the exit condition kicks in and the Taylor rule is

$$
r(0) = \begin{cases} 
\rho + \phi \pi(0) + v & \text{if } \rho + \phi \pi(1) + v > 0 \text{ and } \pi(0) \geq 0, \\
0 & \text{otherwise.}
\end{cases} \quad (A5.12)
$$

The graphs of the Fisher equation and the Taylor rule as shown in Appendix Figure 4c. The difference from the previous figure is that the slope of the Fisher equation is $0 < q < 1$ rather than $1$, and, with $v > 0$, the two graphs have only one intersection, at point C in the figure.

Appendix Table 1 shows the response of the monetary policy regime $s_t$, the inflation rate $\pi_t$, and the nominal rate $r_t$ for a realization of the state of the world that starts with state 0 and switches to state 1 in period $t = 3$, with $v_t$, which has been constant at $v > 0$, suddenly drops to 0 at $t = 3$. In date 0, the monetary policy regime $s_0$ was $Z$ perhaps because the real interest rate was negative. In period 1, the real rate becomes positive but, for reasons explained above in (b), the economy remained trapped in the liquidity trap. In periods $t = 1$ and 2, the shadow Taylor rate $\tilde{r}_t$ equals $\rho + \phi \pi_t + v = -\left(\frac{\phi}{q} - 1\right)\rho + v$, which may or may not be positive. Even when it is positive, the monetary policy regime $s_t$ is $Z$ by (A5.8) because the inflation rate is negative at $-\rho/q$.

Note: Estimation by the ML (maximum likelihood) method described briefly in the text and more fully in Appendix 4. $t$-values in brackets and standard errors in parentheses. The Taylor rule is described as follows:

(censored Taylor rule) $r_t = \begin{cases} \rho tr_t^* + (1 - \rho_r)r_{t-1} + \nu_t, & \nu_t \sim \mathcal{N}(0, \sigma_r^2) \quad \text{if } s_t = P, \\ \bar{r}_t, & \text{if } s_t = Z, \end{cases}$

(desired Taylor rate) $r_t^* \equiv \alpha_r^* + \beta_r^* \begin{bmatrix} \pi_t \\ \nu_t \end{bmatrix},$

where the regime $s_t$ is given by

$\begin{cases} P \text{ if } \rho tr_t^* + (1 - \rho_r)r_{t-1} + \nu_t > \bar{r}_t, \\ \text{shadow Taylor rate} \\ Z \quad \text{otherwise.} \end{cases}$

$\begin{cases} P \text{ if } \rho tr_t^* + (1 - \rho_r)r_{t-1} + \nu_t > \bar{r}_t \text{ and } \pi_t \geq \bar{\pi} + \nu_{\pi_t}, \\ \nu_{\pi_t} \sim \mathcal{N}(0, \sigma_{\pi_t}^2), \\ \text{period } t \text{ threshold} \\ Z \quad \text{otherwise.} \end{cases}$

The intercept $\alpha_r^*$ in the desired Taylor rate depends on: the Mieno dummy (1 for December 1989-June 1991, 0 otherwise), the banking crisis dummy (1 for September 1995-July 1998, 0 otherwise), and the trend growth rate (the 12-month growth rate of potential output). The inflation and output coefficients are the first and second element of $\beta_r^*$. The speed of adjustment is the $\rho_r$ in the shadow rate defined above.
Table 5: Excess Reserve Supply Equation

</tr>
</tbody>
</table>

**Note:** Estimation by OLS. $t$-values in brackets and standard errors in parentheses. $m_t$ is the exces reserve rate, $\pi_t$ is the 12-month inflation rate to month in percents $t$, $x_t$ is the output gap in percents, $\sigma_s$ (standard deviation of the error) is estimated as $\hat{\sigma}_s = \sqrt{SSR/n}$ where $n$ is the sample size. The standard error of $\hat{\sigma}_s$ is calculated as $\frac{\hat{\sigma}_s}{\sqrt{n}}$.

</tbody>
</table>

Note: Estimation by OLS. $t$-values in brackets. $p$ is the monthly inflation rate in percents per year, $x$ is the output gap in percents, $r$ is the policy rate in percents per year, $m$ is the excess reserve rate (defined as the log of the ratio of actual to required reserves), and $g$ is the trend growth rate (the 12-month growth rate in percents of potential output). The Mieno (anti-bubble) dummy (1 if December 1989 $\leq t \leq$ June 1991) and the banking crisis dummy (1 if September 1995 $\leq t \leq$ July 1998) are included in the regressions on lagged subsample P but their coefficients are not reported here; they are not significantly different from zero. There is no need to include those dummies on lagged subsample Z because their value is zero. The value of $r_{t-1}$ is 0 (percent) for (QE1 and) QE2, and 0.1 (percent) for QE3.

</tbody>
</table>

Note: Estimation by OLS on the 112 observations consisting of QE2 (March 2001 - June 2006) and QE3 (December 2008 - December 2012). $t$-values in brackets and standard errors in parentheses. $p$ is the monthly inflation rate in percents per year, $x$ is the output gap in percents, $m$ is the excess reserve rate (defined as the log of the ratio of actual to required reserves). For the additional variable, “spread” is the excess of the zero-coupon 10-year long term yield over the policy rate, in annual percents. The percentage change in the Yen/Dollar exchange rate is defined as 100 times the log difference.
Table 8: Inflation and Output Reduced Form, with Occasionally Positive Excess Reserve Demand

</tbody>
</table>

Note: Estimation by OLS. $t$-values in brackets. $p$ is the monthly inflation rate in percents per year, $x$ is the output gap in percents, $r$ is the policy rate in percents per year, $m$ is the excess reserve rate (defined as the log of the ratio of actual to required reserves), and $g$ is the trend growth rate (the 12-month growth rate in percents of potential output). The banking crisis dummy (1 if September 1995 ≤ $t$ ≤ July 1998) is included in the regressions on lagged subsample P but its coefficient is not reported here. The trend growth rate $g_t$ is excluded for lagged subsample W to avoid near-multicollinearity with the constant.
